shown in Figs. 45 and 46. Some of these are discussed later in this section. The general equations of balance, Eqs. (39) and (40), are valid for all of these.

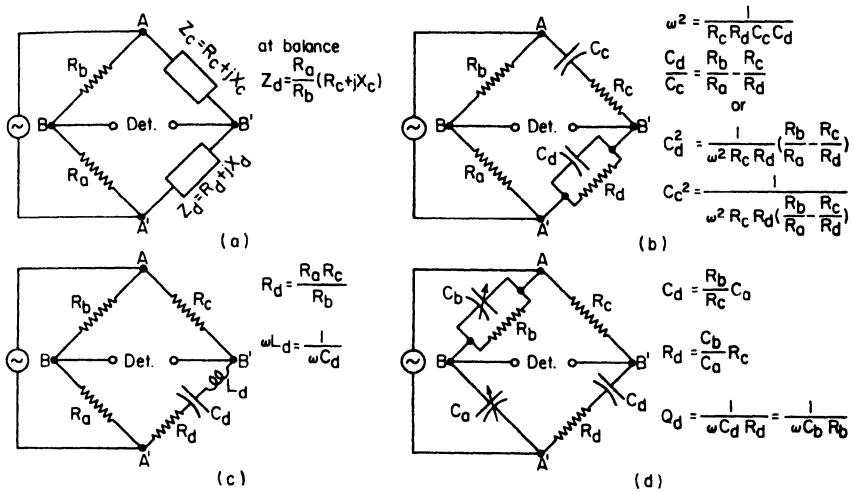
37. Common Forms of Bridges and Their Uses. One of the most common forms of the Wheatstone bridge is the *resistance-ratio bridge*. Here (Fig. 45*a*) two adjacent arms, called the ratio arms, contain pure resistances. The impedances in the other two arms must have the same sign of reactance for the bridge to balance. When the


FIG. 45. (*a*) Resistance-ratio bridge; (*b*) Wien bridge; (*c*) resonance bridge; (*d*) Schering bridge.

bridge is balanced the phase angles of the two impedances are equal and their magnitudes are in the same ratio as the resistances in the ratio arms:

$$\frac{R_d}{X_d} = \frac{R_c}{X_c} \tag{41a}$$

$$\frac{|Z_d|}{|Z_c|} = \frac{R_a}{R_b} \tag{41b}$$

The balance condition can also be expressed as

$$\frac{R_d}{R_c} = \frac{R_a}{R_b} \tag{42a}$$

$$\frac{X_d}{X_c} = \frac{R_a}{R_b} \tag{42b}$$

This bridge is useful for measuring an inductance in terms of another inductance or a capacitance in terms of another capacitance but cannot be used to measure an inductance in terms of a capacitance in an adjacent arm or vice versa.

The *Wien bridge* (Fig. 45*b*) is a special case of the resistance-ratio bridge which permits two capacitances to be compared if all the resistances in the bridge are known. When the bridge is balanced

$$\omega^2 = \frac{1}{R_c R_d C_c C_d} \tag{43a}$$

and

$$\frac{C_d}{C_c} = \frac{R_b}{R_a} - \frac{R_c}{R_d} \tag{43b}$$

Both the capacitances can be computed from the resistances and the frequency if the frequency is also known. Solving Eqs. (43a) and (43b) for C_d and C_c yields

$$C_d^2 = \frac{1}{\omega^2 R_c R_d}\left(\frac{R_b}{R_a} - \frac{R_c}{R_d}\right) \tag{44a}$$

and

$$C_c^2 = \frac{1}{\omega^2 R_c R_d[(R_b/R_a) - (R_c/R_d)]} \tag{44b}$$

The Wien bridge also furnishes a convenient means of determining frequency in the a-f range. The frequency is measured in terms of resistance and capacitance as indicated in Eq. (43a). In a frequency meter of this type C_d is usually made equal to C_c and the two are "ganged" together so that the frequency at which a null occurs varies linearly with capacitance. This frequency meter, therefore, covers a much wider frequency range than does an LC meter employing the same capacitor since the frequency of the LC meter varies as the square root of the capacitance. It is also convenient to make R_d equal to R_c, in which case Eq. (43b) requires that

$$R_b = 2R_a$$

when Eq. (43a) reduces to

$$f = \frac{1}{2\pi R_d C_d} \tag{45}$$

R_c and R_d can be changed in increments to increase the frequency range.

The *resonance bridge* (Fig. 45c) is another form of the resistance-ratio bridge. Three of the arms are pure resistances; therefore Z_d must be real when the bridge is balanced. The balance equations are

$$R_d = \frac{R_a}{R_b} R_c \tag{46a}$$

$$\omega L_d = \frac{1}{\omega C_d} \tag{46b}$$

The resonance bridge is used to measure inductance in terms of capacitance or vice versa. It can also be used to measure frequency in terms of inductance and capacitance.

The *Schering bridge* (Fig. 45d) is used for measuring capacitance and resistance in terms of the same quantities. The balance equations are

$$C_d = \frac{R_b}{R_c} C_a \tag{47a}$$

and

$$R_d = \frac{C_b}{C_a} R_c \tag{47b}$$

Usually R_b and R_c are fixed and C_a and C_b are made variable. This permits both the capacitive and resistive components of the unknown impedance Z_d to be balanced out by varying capacitors. With R_b and R_c fixed, C_a can be calibrated to read directly the unknown capacitance. C_b can then be calibrated to read directly the Q or the dissipation factor $D = 1/Q$ of the unknown capacitor at one frequency:

$$Q_d = \frac{1}{\omega C_d R_d} = \frac{1}{\omega C_b R_b} \tag{48}$$

The Schering bridge, therefore, furnishes a convenient means for measuring the capacitance and dissipation factor of capacitors.

The bridges previously discussed are used for comparing two impedances with the same sign of reactance. Often, however, it is convenient to compare an impedance

with another having the opposite sign of reactance. For example, capacitors can be made with much higher quality factors than can coils and hence represent idealized circuit elements much more closely. Therefore, inductance is often measured on a bridge which employs a capacitor as the standard of comparison. When impedances with opposite signs of reactance are compared they must either be placed in the same arm of the bridge (resonance bridge) or in opposite bridge arms—never in adjacent arms.

One of the simplest bridges for comparing impedances with unlike reactances (Fig. 46a) places them in opposite arms with pure resistances in the other two arms.
FIG. 46. (a) Bridge for comparing impedances with opposite signs of reactance; (b) Maxwell bridge; (c) Hay bridge with parallel inductance and resistance; (d) Hay bridge with series inductance and resistance; (e) Owen bridge.

Both the *Maxwell* and *Hay bridges* are of this form. This general form of bridge corresponds to the resistance-ratio bridge for comparing reactances with like signs. Since the product R_aR_c is real, Z_b and Z_d must have phase angles opposite in sign and of the same magnitude. The balance equations are

$$\frac{|X_d|}{R_d} = \frac{|X_b|}{R_b} \tag{49a}$$

and

$$|Z_d|\,|Z_b| = R_aR_b \tag{49b}$$

When neither Z_d nor Z_b contains both L and C, Eq. (49a) is equivalent to

$$Q_d = Q_b \tag{50}$$

The balance conditions can also be expressed as

$$R_bR_d - X_bX_d = R_aR_c \qquad (51a)$$
$$R_bX_d + R_dX_b = 0 \qquad (51b)$$

The Maxwell bridge (Fig. 46*b*) is used for measuring the inductance and Q of coils in terms of capacitance and resistance. The standard capacitor C_b is shunted with a resistance. The equations of balance are

$$R_d = \frac{R_aR_c}{R_b} \qquad (52a)$$

$$L_d = R_aR_cC_b \qquad (52b)$$

This bridge may be used in either of two ways. In one, a fixed standard capacitor C_b is used and the reactive balance is obtained by varying either R_a or R_c. The resistive balance is then obtained by adjusting R_b. The resistive balance is dependent on the reactive balance as can be seen from Eqs. (52) but the method has the advantage that R_a (or R_c) can be calibrated to read directly in inductance (independent of frequency) while R_b can be calibrated to read Q_d at any one frequency:

$$Q_d = \frac{\omega L_d}{R_d} = \omega C_b R_b \qquad (53)$$
$L' = L\left(\frac{Q^2+1}{Q^2}\right)$, $R' = R(Q^2+1)$, $Q = \frac{\omega L}{R} = \frac{R'}{\omega L'}$

Fig. 47. Approximate equivalent circuits of a coil far below its resonant frequency.

R_a and R_c are held constant in the second way of using the Maxwell bridge while C_d is made variable. This method has the advantage that the resistive and reactive balances are independent. C_b and R_b can now be calibrated so that the bridge reads directly in inductance and resistance. However, R_b cannot be calibrated to read Q_d.

It should be noted here that the representation of a coil by an inductance and a resistance is approximate and is valid only at frequencies far below the self-resonant frequency of the coil (see Sec. 28). Moreover, at any one frequency we are at liberty to represent the coil either by a series combination of inductance and resistance or by a parallel combination (Fig. 47). The Qs given by the two representations are identical but the inductances are not. The two representations are related by the equations

$$R' = R(Q^2 + 1) \qquad (54a)$$

$$L' = L\left(\frac{Q^2 + 1}{Q^2}\right) \qquad (54b)$$

$$Q = \frac{\omega L}{R} = \frac{R'}{\omega L} \qquad (54c)$$

If $Q^2 \gg 1$ the factor

$$\frac{Q^2 + 1}{Q^2} \doteq 1$$

and

$$L' \doteq L$$

When $Q = 10$, L and L' differ by only 1 per cent and when $Q = 33$ they differ by only 0.1 per cent.

The *Hay bridge* (Fig. 47*c*), which differs from the Maxwell bridge only in that the capacitance-resistance combination in arm *b* is in series instead of in shunt, is also used to measure the inductance and Q of coils. In contrast to the Maxwell bridge, which is usually calibrated to read the inductance of a series RL representation of the coil, the Hay bridge can be conveniently calibrated to read the inductance of a paral-

lel RL representation. The balance equations are

$$R_d' = \frac{R_a R_c}{R_b} \tag{55a}$$

$$L_d' = R_a R_c C_b \tag{55b}$$

$$Q_d = \frac{R_d'}{\omega L'} = \frac{1}{\omega C_b R_b} \tag{55c}$$

The bridge dials can be calibrated to read L' and Q directly in a manner similar to that done with the Maxwell bridge.

38. Bridge Sensitivity and Equivalent Input and Output Circuits. The accuracy with which a bridge can be balanced or the sensitivity with which a small change in the impedance in one of the arms can be detected is determined by the power output of the oscillator, the sensitivity of the detector, and the rate of change of unbalance voltage with change in impedance. This sensitivity can be computed from the approximate equivalent circuits of the bridge valid for the case where the bridge is near balance. In the bridge circuit of Fig. 48*a* suppose that the impedances Z_a, Z_b, etc., are the values in the arms under balanced conditions and that ΔZ_d represents a small change in Z_d from the balanced condition.

When the bridge is balanced the potential difference between terminals BB' is zero so that this pair of terminals may either be short-circuited or be left as an open circuit without any effect on the input impedance between terminals AA'. The equivalent input impedance is therefore either

$$Z_{\text{input}} = \frac{(Z_a + Z_b)(Z_c + Z_d)}{Z_a + Z_b + Z_c + Z_d} \tag{56a}$$

or

$$Z_{\text{input}} = \frac{Z_a Z_d}{Z_a + Z_d} + \frac{Z_c Z_b}{Z_c + Z_b} \tag{56b}$$

The two forms are, of course, equivalent under balanced conditions and with Eq. (39) both reduce to

$$Z_{\text{input}} = \frac{Z_d(Z_a + Z_b)}{Z_a + Z_d} \tag{56c}$$

which is sometimes more convenient to use. In fact, since the four impedances of a balanced bridge are not independent but must satisfy the conditions of Eq. (39) any one of the four can be eliminated from Eq. (56*a*) or Eq. (56*b*) to give other expressions of the same form as Eq. (56*c*).

Under balanced conditions the potential between terminals AA' caused by a generator across terminals BB' must be zero from the reciprocity theorem. Therefore, the output impedance of a bridge can be written either as

$$Z_{\text{output}} = \frac{(Z_b + Z_c)(Z_a + Z_d)}{Z_a + Z_b + Z_c + Z_d} \tag{57a}$$

or

$$Z_{\text{output}} = \frac{Z_a Z_b}{Z_a + Z_b} + \frac{Z_c Z_d}{Z_c + Z_d} \tag{57b}$$

or

$$Z_{\text{output}} = \frac{Z_b(Z_a + Z_d)}{Z_a + Z_b} \tag{57c}$$

The open-circuited voltage between terminals BB' is the potential difference between these points due to the unbalance in the bridge and is

$$V_{0c} = V' \frac{Z_c Z_d}{(Z_c + Z_d)^2} \frac{\Delta Z_d}{Z_d} \tag{58a}$$
FIG. 48. Schematic diagram of bridge with generator and detector. (*a*) Equivalent input and output circuits of a balanced Wheatstone bridge; (*b*) equivalent input circuit at balance; (*c*) equivalent output circuit near balance.

With the aid of Eq. (39) the open-circuit voltage can also be expressed in terms of the impedances in the other two arms of the bridge:

$$V_{0c} = V' \frac{Z_a Z_b}{(Z_a + Z_b)^2} \frac{\Delta Z_d}{Z_d} \tag{58b}$$

Usually only the magnitude of V_{0c} is of interest.

From Eqs. (57) and (58) it is seen that the Thévenin equivalent output circuit for the bridge is that shown in Fig. 48*c*.

The equivalent circuits can be used to compute the signal generator voltage and detector sensitivity required to give any desired accuracy $\left|\frac{\Delta Z_d}{Z_d}\right|$ in the determination of Z_d. Suppose, for example, it is desired to find the generator voltage required to give a bridge sensitivity $\left|\frac{\Delta Z_d}{Z_d}\right|$ of 0.1 per cent with a detector having 5 μv sensitivity. First use the output equivalent circuit (Fig. 48c) and compute V' setting $V_{\text{det}} = 5 \times 10^{-6}$ volt and $\left|\frac{\Delta Z_d}{Z_d}\right| = 0.001$. Next, by means of the equivalent input circuit (Fig. 48b), compute V_0 using the value of V' just computed. The required open-circuit generator voltage to give the desired bridge sensitivity is V_0.

A consideration of the equivalent circuits of a bridge indicates the desirability of matching both the generator and the detector impedances to the input and output impedances, respectively, to optimize the bridge sensitivity. Aside from matching, it can be seen from Eq. (58b) that the sensitivity of a resistance-ratio bridge is maximized when the resistances in the ratio arms are made equal. Equation (58) also shows that the per unit sensitivity to unbalance of the smaller component of impedance is very much poorer than that for the larger when the ratio of the two components is large. For example, the sensitivity to unbalance of the resistive component of a high-Q coil is the same as that for the reactive component. However, the resistance is only $1/Q$ times as large as the reactance; therefore

$$\frac{\Delta R}{R} \doteq Q \frac{\Delta X}{X} \tag{59}$$

For the same reason the inductive balance is much more sensitive, in per cent, than the Q balance when a high-Q coil is measured on a Maxwell or a Hay bridge (Sec. 37). The relation is

$$\frac{\Delta Q}{Q} \doteq Q \frac{\Delta L}{L} \tag{60}$$

BRIDGE TECHNIQUES

39. Signal Generators and Detectors. Any oscillator or signal generator which will operate at the desired frequency and which will furnish sufficient power to give the required bridge sensitivity can be used as a signal source for bridge measurement. If the detector is a broad-band instrument, such as a VTVM, or a telephone headset commonly used at audio frequencies, then the harmonic output of the bridge oscillator should be low. The requirement of low harmonic content in the signal from the bridge oscillator is imposed because the impedances in the bridge arms change with frequency and, therefore, a bridge will not, in general, balance at the same dial settings for more than one frequency. The requirement for good wave form is not important if a narrow-band detector, such as a communication receiver, is used. At radio frequencies the signal may be amplitude-modulated with an audio tone to facilitate detection.

Any instrument sensitive to small voltages may be used as a bridge detector. A telephone headset is often used at audio frequencies and a sensitive VTVM may be used at all frequencies. A communications receiver whose sensitivity is of the order of a microvolt makes an excellent detector at radio frequencies. When a receiver is used as a bridge detector the automatic-volume-control circuits should be disabled. Narrow-band high-gain r-f receivers designed for use as bridge detectors are commercially available.

The power output of the oscillator and sensitivity of the detector required to give any bridge sensitivity can be computed from the equivalent circuits of Sec. 38.

In addition to having sufficient power and sensitivity, the oscillator and detector must be well shielded from each other for the true balance point to be detected. Poor shielding results in two effects: (1) the null is partially masked so that the detector

output shows a minimum rather than a true null, and (2) since the phase of the signal from the bridge varies very rapidly with bridge setting in the vicinity of a null, the minimum detector output occurs when the signal from the bridge tends to cancel the leakage signal. At radio frequencies it is necessary to use shielded cables to connect the detector and the oscillator to the bridge.

40. Bridge Transformers. Most signal generators and bridge detectors have large stray capacitances from the terminals to ground and in many cases one of the terminals is at ground potential. These stray capacitances appear across the bridge arms and at
FIG. 49. (*a*) Schematic diagram showing effect of terminal capacitances in generator and detector; (*b*) bridge with shielded transformer; (*c*) typical transformer.

radio frequencies lead to erroneous results; even at audio frequencies they may cause serious errors. The use of both a detector and a signal generator with one terminal of each connected to ground is actually equivalent to grounding two corners of the bridge. Some provision must therefore be made for isolating the bridge from one of these equipments and a shielded transformer is usually used for this purpose. The transformer also permits the signal generator or detector to be matched to the input or output impedance of the bridge and thus increases the sensitivity.

The stray capacitances of the detector and oscillator in an unshielded bridge are illustrated in Fig. 49*a*, where C_1, C_2, C_3, and C_4 are the stray capacitances in question. Since point A' is grounded, C_1 has no effect. Likewise, C_3 is shunted across the generator terminals and has no effect on the bridge balance. On the other hand, C_2 and C_4 are shunted

across Z_a and Z_d, respectively, and enter into the balance equations of the bridge. The bridge balance is therefore dependent upon the stray capacitances in the detector circuit. Had point B been chosen for the ground point, then the stray capacitances in the generator would have entered into the balance equations.

The effect of the stray capacitances of the generator or detector can be removed by the use of a transformer with a shield between the windings (Fig. 49*b*). Since the capacitance between the primary and secondary winding can be reduced to a few tenths of 1 $\mu\mu$f the generator or detector capacitances to ground become negligible. The stray capacitances of the transformer secondary will now appear across the arms. The transformer can be designed, however, so that these stray capacitances are small and, moreover, they will remain fixed and can be included as part of the impedance in the respective arms. A typical shielded transformer is shown in Fig. 49*c*.

41. Bridge Errors. The lead inductances and shunt capacitances associated with the impedances of the bridge arms cause the most serious errors in bridge measurements. The effect of these stray reactances increases with frequency and is particularly important at radio frequencies. Even at audio frequencies serious errors may result if corrections are not made for these quantities. At radio frequencies bridge circuits must be designed to minimize the magnitudes of these stray reactances and provisions must be made for estimating their values so that corrections can be made in the bridge measurements.

Stray capacitances across the various bridge arms can be minimized to some extent by careful shielding. The most important function served by shielding, however, is to fix the magnitudes of these stray capacitances and to place them across points in the circuit where they can most easily be compensated or for which the errors introduced can most easily be corrected. Shielding, of course, includes the use of a shielded transformer as described in Sec. 40. An example of a shielded bridge is shown in Fig. 50.

Substitution of the unknown impedance in place of a standard in one arm of a balanced bridge provides one method for minimizing the effect of stray reactance. In this manner only the difference between the standard and the unknown need be measured. This method is nearly always used at high radio frequencies.
Fig. 50. General Radio shielded bridge.
Fig. 51. Substitution method.

As an example of the substitution method, consider the Schering bridge of Fig. 51 where the standard impedance is a short circuit. The bridge is first balanced with a short circuit across the "unknown" terminals Z_u. The unknown impedance is inserted and the bridge is rebalanced. From the two sets of balance conditions the components of the unknown

impedance are found to be

$$R_u = \frac{R_c}{C_a}(C_b'' - C_b') \tag{61a}$$

and

$$X_u = \frac{1}{\omega}\left(\frac{1}{C_d''} - \frac{1}{C_d'}\right) \tag{61b}$$

where primes and double primes indicate the initial and final values of a parameter, respectively.

In this illustration the unknown impedance was inserted in series with the impedance in the bridge arm. It is also possible to place the unknown impedance in parallel with one of the arms, in which case the initial balance is usually made with the "unknown" terminals left as an open circuit.

42. Direct Capacitance. When a capacitor has terminal capacitances to a surrounding shield or to ground it can be represented as a three-terminal capacitor (Fig. 52*a*). The capacitance C_{12} is called the *direct capacitance* between terminals 1 and 2. The total capacitance between terminals 1 and 2 is the sum of the direct
FIG. 52. (*a*) Shielded capacitor; (*b*) interelectrode capacitances of triode; (*c*) capacitance network and three-terminal equivalent network.

capacitance and the two capacitances C_{13} and C_{23} in series; and if the capacitor is connected to a capacitance bridge by terminals 1 and 2 with terminal 3 left disconnected the total capacitance will be the quantity measured. Often, however, the direct capacitance is the parameter of interest. The requirement for measuring direct capacitance in the presence of terminal capacitances may arise from any network which has more than two terminals. For example, any of the interelectrode capacitances of a triode tube (Fig. 52*b*) is the direct capacitance between two electrodes and must be measured in the presence of the other two interelectrode capacitances. Moreover, for the purpose of measuring direct capacitance, any network of capacitors can be reduced to a three-terminal network of the form shown in Fig. 52*a*, by connecting all the terminals together except the pair between which the direct capacitance is to be measured (Fig. 52*c*). The use of a guard circuit enables both direct capacitance and its dissipation factor to be measured.

43. Guard Circuit. When the four corners of a bridge are connected through impedances to a fifth point (Fig. 53*a*) the balance conditions will not be changed if the point P is kept at the same potential as the two corners B and B'. No potential difference exists across Z_2 and Z_4 in this case and they may be removed from the circuit leaving Z_1 in series with Z_3 across the generator terminals and the bridge balance unaffected. One set of conditions which gives a null on the detector is therefore

$$\frac{Z_a}{Z_b} = \frac{Z_d}{Z_c} = \frac{Z_1}{Z_3} \tag{62}$$

But there is a second set of conditions which gives a null on the detector. If the detector is connected across terminals AA' and the generator across BB' the detector

will show a null when

$$\frac{Z_a}{Z_d} = \frac{Z_b}{Z_c} = \frac{Z_2}{Z_4} \tag{63}$$

for the same reason given in obtaining Eq. (62). The reciprocity theorem, however, requires that the detector show a null if the generator and detector are interchanged. Therefore, the conditions of Eq. (63) also give a null when the detector is connected across terminals BB' and the generator across terminals AA'.

Both Eq. (62) and Eq. (63) contain the balance condition of the bridge without the guard circuit. Therefore, the balance of the bridge will be unaffected by the guard circuit if the guard circuit meets the requirements of either Eq. (62) or Eq. (63). Usually in using a guard circuit Z_1 and Z_3, which are across the generator, are balanced to satisfy Eq. (62), in which case these two impedances are often called the guard circuit while the impedances across the detector Z_2 and Z_4 are called *coupling impedances*.
FIG. 53. (*a*) Schematic circuit; (*b*) Schering bridge and guard circuit for measuring direct capacitance.

When direct capacitance is measured by means of a guard circuit the two terminals between which the direct capacitance is to be measured are connected to the bridge in the usual manner so that the direct capacitance forms one arm of the bridge (Fig. 53*b*). The third terminal is then connected to point P.

The detector is first connected between points P and B' and the guard circuit is balanced. Then, by means of switch S, the detector is connected between points B and B' and the bridge is balanced. At balance the usual balance equations for the bridge apply, which for the Schering bridge of Fig. 53*b* are

$$C_d = \frac{R_b}{R_c} C_a \tag{64a}$$

$$Q_d = \frac{1}{\omega C_b R_b} \tag{64b}$$

In the particular case shown in Fig. 53*b* the guard-circuit balance is independent of the bridge balance since both Z_c and Z_d are held constant. Therefore, both the guard circuit and bridge need to be balanced only once, if the guard circuit is balanced first, to give a balance for both positions of the switch. If either Z_c or Z_d is changed in the process of balancing the bridge, as will occur when a substitution method is used, then the guard circuit and bridge balances are not independent and alternate readjustments of the guard circuit and bridge must be made until there is a balance for both positions of the switch.

44. Wagner Ground. As discussed in Sec. 40 the capacitances between ground and the terminals of the signal generator and the detector appear across some of the bridge arms and cause errors unless a shielded transformer is used. In making impedance measurements on a resistance-ratio bridge at audio frequencies satisfactory accuracy can often be obtained without the use of a transformer by means of a *Wagner ground* (Fig. 54). In using this circuit both the signal generator and the detector are left ungrounded. C_1 and C_3 are the terminal capacitances of the generator and C_2 and C_4 are those of the detector. These capacitances form a guard circuit which, if properly balanced, will leave the bridge balance unaffected. A low-impedance potentiometer with the movable tap grounded is connected across the generator terminals to provide a means of balancing the guard circuit. This potentiometer is in parallel with C_1 and C_3 between points A and A' and the movable tap is at the potential of point P. Since the impedance of the potentiometer is low compared with that of C_1 and C_3 the guard circuit is approximately balanced when

FIG. 54. Wagner ground.

$$\frac{R_1}{R_3} = \frac{R_a}{R_b} \tag{65}$$

The guard circuit and bridge are alternately adjusted with the switch S connected to ground and to point B', respectively, until a null exists for both positions of the switch. The usual balance equations for the bridge are then applicable.

A capacitive voltage divider can be used in place of the potentiometer shown in Fig. 54.

45. Mutual Inductance. In the measurement of mutual inductance a situation arises somewhat analogous to the measurement of direct capacitance (Sec. 42). In addition to the mutual inductance between the two windings of a transformer there are always associated with it the self-inductances of each of the windings. Although the usual transformer is a four-terminal network (Fig. 55*a*) one can connect terminals 3 and 4 together for the purpose of measurement. The equivalent circuit valid at frequencies where the shunt capacitances may be neglected is then as shown in Fig. 55*b*. As in the case of direct capacitance this is a three-terminal network; it is a T network, however, instead of a Δ network.

FIG. 55. Mutual inductance and equivalent circuit.

In measuring mutual inductance on a bridge the transformer is connected so that the T junction in the equivalent circuit forms one corner of the bridge with the mutual inductance forming part of one bridge arm and one of the other branches of the T forming part of an adjacent arm. The third branch of the T is then in series with either the detector or the generator where it does not enter into the balance equations.
FIG. 56. Carey-Foster bridge. (a) Schematic diagram; (b) equivalent circuit.
FIG. 57. Campbell bridge. (a) Schematic diagram; (b) equivalent circuit.

Two bridges commonly used for measuring mutual inductance are the *Carey-Foster bridge* (Fig. 56) and the *Campbell bridge* (Fig. 57). The balance equations for the Carey-Foster bridge are

$$M = R_a R_p C_b \tag{66a}$$

and

$$M = \frac{R_a L_p}{R_a + R_b} \tag{66b}$$

The mutual inductance enters into both the resistive and the reactive balances but is measured in terms of either the inductance or the resistance of the transformer primary, both of which must be measured on another bridge, by the Maxwell bridge of Fig. 46*b*, for example. In the Campbell bridge the self-inductance again enters into the determination of the mutual inductance. The balance equations for this bridge are

$$R_b R_d = R_a R_p \tag{67a}$$

and

$$M = \frac{R_a L_p - R_b L_d}{R_a + R_b} \tag{67b}$$

Changing the detector connection from terminal 2 to terminal 3 with switch S, however, permits L_p to be compared with L_d in a resistance-ratio bridge. The Campbell bridge, therefore, has the advantage that, although M is measured in terms of L_p, the primary inductance L_p can be determined by a second measurement on the same bridge. The fact that M is determined as the difference of two larger quantities, however, limits the accuracy of the measurements.
FIG. 58. Felici mutual-inductance balance.

An unknown mutual inductance can also be compared with a known calibrated variable mutual inductance on the *Felici mutual-inductance balance* (Fig. 58). In this circuit the two transformer primaries are connected in series to the signal source so that the same current flows through each primary. The detector is connected across the transformer secondaries, which are also connected in series. The secondaries, however, are connected so that the induced voltages are in opposition. The detector current is a null when the two induced voltages $j\omega M_0 I_p$ and $j\omega M_u I_p$ are equal. The balance condition is therefore

$$M_u = M_0 \tag{68}$$

46. Incremental Inductance. The inductance offered to the alternating component of current by an iron-cored coil which is used as a power-supply filter is a function of the direct current flowing through the coil. This inductance is called the *incremental inductance.*

In measuring incremental inductance it is necessary to send a direct current through the coil and to arrange the circuit so that this magnetizing current can be measured.
FIG. 59. Circuits for measuring incremental inductance. (*a*) Hay bridge; (*b*) Owen bridge.

The Hay bridge (Fig. 46*d*) or the Owen bridge (Fig. 46*e*) are usually chosen because the series capacitors block the direct current and permit it to be metered externally (Fig. 59).

T NETWORKS

In addition to the four-impedance bridge circuit two other null-type networks are sometimes used for impedance measurements. One of these is the *twin-T* or *parallel-T* network (Fig. 60*a*). The other is the bridged-T network (Fig. 60*b*). Both these cir-

cuits have the advantage over the bridge circuit that the generator and the detector have a common terminal which can be grounded. Hence a shielded transformer is not necessary.

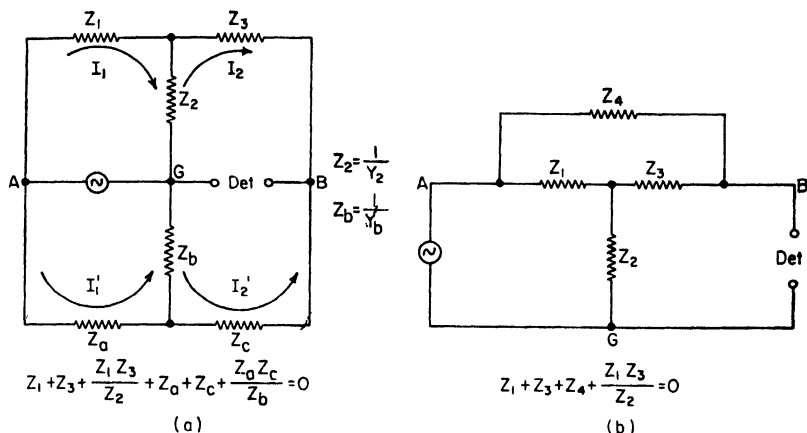
47. Twin-T Network. When a null exists at the detector there is no potential difference between points B and G of the network shown in Fig. 60a. Therefore, the detector terminals may be short-circuited or left as an open circuit without affecting the condition of balance. In finding the balance condition it is convenient to assume


FIG. 60. T networks. (a) Twin-T circuit; (b) bridged-T circuit.

that a short circuit is across these terminals. The two Ts are then isolated and the output currents I_2 and I_2' can be found separately:

$$I_2 = \frac{VZ_2}{Z_1Z_2 + Z_2Z_3 + Z_1Z_3} \tag{69a}$$

$$I_2' = \frac{VZ_b}{Z_aZ_b + Z_bZ_c + Z_aZ_c} \tag{69b}$$

The null occurs when no current flows through the short circuit:

$$I_2 + I_2' = 0 \tag{70}$$

The balance condition is therefore

$$Z_1 + Z_3 + \frac{Z_1Z_3}{Z_2} + Z_a + Z_c + \frac{Z_aZ_c}{Z_b} = 0 \tag{71}$$

Since the impedances of which the network is composed are complex quantities, Eq. (71) actually represents a pair of equations in real variables. Moreover, it should be noted that although all the impedances contain positive real parts the product terms Z_1Z_3/Z_2 and Z_aZ_c/Z_b can have negative real parts so that the condition corresponding to the real part of Eq. (71) can be realized. The condition corresponding to the imaginary part of Eq. (71) can, of course, be realized since the component impedances can have either sign of reactance. In contrast to the bridge circuit the twin-T network cannot be used for d-c resistance measurements since a network composed only of resistances will not satisfy the conditions of balance expressed in Eq. (71).

48. Bridged-T Network. The bridged-T circuit (Fig. 60b) is a degenerate form of the twin-T network in which Z_b is an open circuit. The balance condition is therefore

given by Eq. (71) if we let $Z_b \to \infty$ and write Z_4 for the series combination $Z_a + Z_c$. The balance condition is

$$Z_1 + Z_3 + Z_4 + \frac{Z_1 Z_3}{Z_2} = 0 \tag{72}$$

49. Commonly Used T Networks. The twin-T circuit shown in Fig. 61 is very often used for measuring the admittance of high-impedance circuits at radio frequencies. This circuit gives good results for frequencies as high as 50 Mc and is more accurate than an r-f bridge when the impedance $1/Y_u$ is high. The balance equations for this circuit are

$$G_2 = \omega^2 C_1 C_3 \left(1 + \frac{C_b}{C_a}\right) R_c \tag{73a}$$

and

$$B_2 = -\omega C_1 C_3 \left(\frac{1}{C_1} + \frac{1}{C_3} + \frac{1}{C_a}\right) \tag{73b}$$

where the admittance between point A and ground is

$$Y_2 = \frac{1}{Z_2} = G_2 + jB_2 \tag{74}$$

As indicated in Fig. 61 a substitution method is nearly always used with this circuit. In this case the initial balance is made with the terminals u and u' left as an open circuit, after which the admittance to be measured Y_u is inserted between terminals u and u' and the circuit is rebalanced. The unknown admittance can be found from the relations

$$G_u = \frac{\omega^2 C_1 C_3 R_c}{C_a} (C_b'' - C_b') \tag{75a}$$

$$B_u = \omega(C_2' - C_2'') \tag{75b}$$

Fig. 61. Twin-T circuit for admittance measurements of high-impedance circuits at radio frequencies.

where the primes indicate values of a parameter at the initial balance and the double primes indicate the value of the same parameter at the final balance. In this arrangement only the circuit elements C_b and C_2 need to be made variable. C_b can be calibrated directly in conductance at any single frequency. The calibrated scale will then vary as the square of the frequency; it is thus seen that the range of conductances which can be measured decreases rapidly as the frequency is decreased. C_2 can be calibrated directly in susceptance at one frequency. The calibration then varies directly as the frequency.

It should be noted that the circuit of Fig. 61 has the advantage that one terminal of each of the variable circuit elements in the bridge and one terminal of the circuit element to be measured as well as one terminal of the generator and one terminal of the detector can all be grounded.

The twin-T network shown in Fig. 62 is equivalent to the Wien bridge (Sec. 37) and has similar balance equations:

$$\omega^2 = \frac{1}{R_b C_a C_c (R_1 + R_3)} \tag{76a}$$

$$\omega^2 = \frac{C_a + C_c}{R_1 R_3 C_2 C_a C_c} \tag{76b}$$

Equating the two expressions for ω^2 obtained from the balance condition gives an expression relating the capacitors and resistors in the network:

$$\frac{C_a + C_c}{C_2} = \frac{1}{R_b}\left(\frac{R_1R_3}{R_1 + R_3}\right) \tag{77}$$

When both the T networks are made symmetrical and when in addition C_2 is made twice C_a and R_1 is made twice R_b then both Eq. (75*a*) and Eq. (75*b*) reduce to the single expression

$$f = \frac{1}{2\pi R_1 C_a} \tag{78}$$

which is identical in form with Eq. (45) for the Wien bridge.
FIG. 62. Twin-T network equivalent to Wien bridge.
FIG. 63. Bridged-T circuit for measuring inductance.

The bridged-T circuit of Fig. 63 is useful for measuring inductance in terms of capacitance and resistance. For the measurement of the incremental inductance (Sec. 46) of iron-cored coils the d-c magnetizing current can be conveniently introduced in series with the a-c voltage, provided a low-resistance path is placed across the detector. The balance equations for this circuit are

$$R_4 = \frac{1}{\omega^2 C_1 C_3 R_2} \tag{79a}$$

$$L_4 = \frac{1}{\omega^2}\left(\frac{1}{C_1} + \frac{1}{C_3}\right) \tag{79b}$$

and

$$Q_4 = \frac{\omega L_4}{R_4} = \omega(C_1 + C_3)R_2 \tag{80}$$

In making measurements with this circuit it is convenient to make C_3 equal to C_1 and to gang them together. The balance equations [Eqs. (79*a*) and (79*b*)] then reduce to

$$R_4 = \frac{1}{\omega^2 C_1^2 R_2} \tag{81a}$$

$$L_4 = \frac{2}{\omega^2 C_1} \tag{81b}$$

and

$$Q_4 = 2\omega C_1 R_2 \tag{82}$$

IMPEDANCE MEASUREMENTS AT V.H.F.

Radio-frequency bridges with lumped circuit elements are useful for impedance measurements up to 150 Mc but above this frequency stray capacitances and inductances cause serious errors. On the other hand, slotted transmission lines become cumbersome below 300 Mc. Two null-type measuring instruments, which are not true bridges, are particularly useful for making impedance measurements in the intervening frequency range. One of these is the General Radio *admittance meter* and the other is the *Byrne bridge*.

50. General Radio Admittance Meter. The General Radio admittance meter is shown schematically in Fig. 64, where the coaxial lines normally used are drawn as two-wire lines. It consists of a transmission-line junction with four arms. Arms A, B,
FIG. 64. General Radio admittance meter.

and C are identical and are terminated in a standard conductance, a standard susceptance, and the unknown admittance, respectively. An r-f source at the desired frequency is connected to the fourth arm. A small loop is located in each of the three symmetrical arms at points very near to, and equidistant from, the junction.

These three loops are connected to a common transmission line and thence to a detector. The current induced in each of these loops is proportional to the currents in the respective arm. The loops in the arms A and B can be rotated to vary the coupling between the loop and the line.

The principle of operation is as follows:

The same r-f voltage V is impressed on each of the arms A, B, C. The resulting currents in the three arms are

$$I_A = VG_s \tag{83a}$$

$$I_B = jVG_s \tag{83b}$$

$$I_C = VY_u = V(G_u + jB_u) \tag{83c}$$

and the current flowing into the detector junction is

$$I_d = V[M_AG_s + jM_BB_s + M_C(G_u + jB_u)] \tag{84}$$

where M_A, M_B, and M_C are the coupling ratios of the three loops. When the output of the detector is zero

$$G_u = \frac{-M_A}{M_C} G_s \tag{85a}$$

and

$$B_u = \frac{-M_B}{M_C} B_s \tag{85b}$$

Note that the measured admittance Y_u is the ratio of current to voltage at the position of the loop (point C). Likewise the standard conductance and susceptance are adjusted so that the ratios of I to V at the loop positions have the standard values.

51. Byrne Bridge. The basic circuit of the Byrne bridge is shown in Fig. 65. The signal generator is connected through a junction which contains two probes. One of these is a capacitive probe which samples the voltage and the other is a small loop whose output is proportional to the current. The coupling between each of these probes and the line can be varied by adjusting the distance between the probe and the center conductor. They are ganged together so that one probe moves toward the center conductor as the other moves away from it. The signals from these two probes are connected to opposite ends of the section of slotted transmission line which is terminated on both ends in its characteristic impedance to make reflections negligible. A movable probe on this line is connected to the detector. The detected signal is thus proportional to the sum of the two waves initiated by the voltage and current probes, respectively.
FIG. 65. Byrne bridge.

When the unknown impedance is a pure resistance the voltage and current at the junction are in phase with each other. However, the current loop is connected in such a manner that the two voltages applied to the opposite ends of the auxiliary section of the line are 180 deg out of phase with each other and a voltage minimum therefore occurs at the mid-point. When the probe coupling is adjusted so that the two voltages are of equal magnitude this minimum becomes a null. The ratio of the magnitudes of the current and voltage, which can be read from the calibrated probes, is then equal to the unknown resistance.

When the unknown impedance is complex the minimum is shifted from the center of the auxiliary line. The distance which the minimum is shifted is proportional to the difference in phase of the voltage and current at the junction and therefore to the phase angle of the impedance. This probe is calibrated to read phase angle directly at one frequency, but since the distance the minimum is shifted is also proportional to the wavelength, a correction factor must be applied at other frequencies. The ratio of the amplitudes of the voltage and current as read from the calibrated probe when the detector output is a null is the magnitude of the unknown impedance.

TRANSMISSION-LINE TECHNIQUES

Under steady-state conditions the voltage on a transmission line can be considered as the sum of two traveling waves, one traveling toward the termination, and the
FIG. 66. Voltage standing-wave pattern on transmission line.

Table 1. Definitions of Symbols

Symbol	Definition
c	shunt capacitance per unit length
e	base of natural logarithms
g	shunt conductance per unit length
l	series inductance per unit length
n	an integer
p	a ratio (Fig. 66)
r	series resistance per unit length
R_c	characteristic resistance
r_1	real part of normalized impedance
s	distance from generator to termination (Fig. 66)
S	voltage-reflection coefficient
t	time
V_i	incident voltage wave (traveling toward termination)
V_r	reflected voltage wave (traveling toward generator)
V_0	voltage at generator end of line
w, w_{min}, w_{SC1}, w_{SC2}, w_{SC}, w', Δw	distance from termination (Figs. 66 and 72)
x	distance from generator (Fig. 66)
x_1	imaginary part of normalized function
y	shunt admittance per unit length
z	series impedance per unit length
Z_c	characteristic impedance
Z_1	normalized impedance of termination
α	attenuation constant
β	phase constant
γ	propagation constant
Γ	voltage-reflection coefficient of termination
δ	width across minimum of voltage distribution (Fig. 66)
ϵ	relative dielectric constant
θ	complex terminal function
λ	wavelength on line
ρ	attenuation function
Φ	phase function
ϕ_c	distortion factor
ψ	phase angle of reflection coefficient
ω	angular frequency

other a reflected wave traveling toward the generator. These two waves mutually reinforce at some points on the line and suffer destructive interference at others. The standing-wave pattern thus formed is determined entirely by the terminating impedance (Fig. 66) at the load end and can be used to find the magnitude and phase angle of this impedance. A section of transmission line properly instrumented so that the voltage distribution along it can be measured forms a very important impedance-measuring instrument at frequencies above 300 Mc. Below this frequency the equipment is cumbersome since a section of line approximately $\pi/2$ long is needed.

Table 2. Important Transmission-line Equations

A. Transmission-line parameters

$$Z_c = \sqrt{\frac{z}{y}}$$ is the characteristic impedance where z and y are the series impedance per unit length and the shunt admittance per unit length, respectively

$$Z_c = R_c(1 - j\phi_c)$$

$$Z_c = R_c\left(1 - j\frac{\alpha}{\beta}\right)$$ for lines with no dielectric losses

Usually $\phi_c \ll 1$ and

$$Z_c \doteq R_c$$

R_c is the characteristic resistance.
For a coaxial line:

$$R_c = \frac{138}{\sqrt{\epsilon}} \log_{10} \frac{b}{a}$$

where a = radius of inner conductor
b = radius of outer conductor
ϵ = relative dielectric constant of dielectric in space between a and b

For two-wire line:

$$R_c \doteq \frac{276}{\sqrt{\epsilon}} \log_{10} \frac{b}{a}$$

where a = radius of wires
b = distance between centers

B. Equations relating to the termination

$$z_1 = \frac{Z}{Z_c}$$ is the normalized impedance of the termination where Z is the impedance of the termination

$$z_1 = r_1 + jx_1$$
$$z_1 = \coth \theta$$

where $\theta = \rho + j\Phi$ = complex terminal function
ρ = attenuation function
Φ = phase function

$$r_1 = \frac{\sinh 2\rho}{\cosh 2\rho - \cos 2\Phi}$$

$$x_1 = \frac{-\sin 2\Phi}{\cosh 2\rho - \cos 2\Phi}$$

$$\rho = \frac{1}{2} \tanh^{-1} \frac{2r_1}{|z_1|^2 + 1}$$

$$\Phi = \frac{1}{2} \tan^{-1} \frac{-2x_1}{|z_1|^2 - 1}$$

$$\Gamma = \frac{z_1 - 1}{z_1 + 1}$$ = voltage-reflection coefficient

$$z_1 = \frac{1 + \Gamma}{1 - \Gamma}$$

$$\Gamma = |\Gamma| e^{j\psi}$$
$$\Gamma = e^{-2\theta}$$
$$|\Gamma| = e^{-2\rho}$$
$$\psi = -2\Phi$$

$$\rho = \frac{1}{2} \ln \frac{1}{|\Gamma|}$$

Table 2. Important Transmission-line Equations (*Continued*)

C. **Equations relating to the input impedance and reflection coefficient at any point along the line**

$$z_1(w) = \coth(\theta + \gamma w)$$

$$r_1(w) = \frac{\sinh 2(\rho + \alpha w)}{\cosh 2(\rho 2\alpha w) - \cos 2(\Phi + \beta w)}$$

$$x_1(w) = \frac{-\sin 2(\Phi + \beta w)}{\cosh 2(\rho + \alpha w) - \cos 2(\Phi + \beta w)}$$

$$\rho + \alpha w = \frac{1}{2}\tanh^{-1}\frac{2r_1(w)}{|z_1(w)|^2 + 1}$$

$$\Phi + \beta w = \frac{1}{2}\tan^{-1}\frac{-2x_1(w)}{|z_1(w)|^2 - 1}$$

$$\Gamma(w) = \frac{z_1(w) - 1}{z_1(w) + 1}$$

$$z_1(w) = \frac{1 + \Gamma(w)}{1 - \Gamma(w)}$$

$$S = \frac{1 + |\Gamma(w)|}{1 - |\Gamma(w)|}$$ is the voltage standing-wave ratio (VSWR)

$$S = \coth(\rho + \alpha w)$$

$$Z = Z_c^2 \frac{Z(w) - Z_{SC}(w)}{Z_c^2 - Z(w)Z_{SC}(w)}$$

where $Z_{SC}(w) = Z_c \tanh \gamma w$ is the impedance at point w with a short-circuit termination. This equation is convenient for computing Z when $Z(w)$ and $Z_{SC}(w)$ have been measured.

$$z_1 = \frac{z_1(w) - \tanh \gamma w}{1 - z_1(w) \tanh \gamma w}$$

For lossless lines:

$$z_1 = \frac{z_1(w) - j \tan \beta w}{1 - jz_1(w) \tan \beta w}$$

$$z_1(w) = \frac{1 + jz_1 \tan \beta w}{z_1 + j \tan \beta w}$$

and

$$z_1 = \frac{1 - jS \tan \beta w_{\min}}{S - j \tan \beta w_{\min}}$$

The last equation is sometimes convenient for computing the impedance of a termination when the VSWR and the position of a minimum are known.

52. Theory of Transmission-line Impedance Measurements.[16,17,18] Before discussing transmission-line techniques for measuring impedance, it is necessary to digress briefly to define several parameters which are needed to describe these techniques. Definitions of the symbols used are shown in Table 1 and the more important equations are given in Table 2.

The electrical characteristics of a two-conductor transmission line are most often described by a pair of complex quantities called the *characteristic impedance* and the *propagation constant.* The characteristic impedance Z_c is the impedance which would be measured at the input terminals to the line if the line extended on indefinitely. It is the ratio of voltage to current in a wave traveling down the line. When a transmission line is terminated in its characteristic impedance the traveling wave is completely absorbed at the termination and the line behaves as if it extends indefinitely. The propagation constant γ describes the propagation of a wave along the semi-infinite line. If the voltage at the input were $V_0e^{j\omega t}$ then the voltage at a point x meters down the line would be $V_0e^{(j\omega t - \gamma x)}$. Since $\gamma = \alpha + j\beta$, the voltage along the line is given by

$$V(x,t) = V_0e^{-\alpha x + j(\omega t - \beta x)} \tag{86}$$

This represents a voltage which is attenuated by a factor $e^{-\alpha x}$ and is retarded in phase by βx radians. The real part of γ is therefore called the *attenuation constant* and the imaginary part is called the *phase constant.*

The distance along the semi-infinite line in which the phase of the traveling wave undergoes a phase shift of 2π radians is called the wavelength. The wavelength λ is related to the propagation constant by

$$\beta\lambda = 2\pi \tag{87}$$

Alternatively, the characteristics of a transmission line can be described by another pair of complex quantities—the series impedance per unit length z and the shunt admittance per unit length y. These two pairs of complex quantities which are commonly used to characterize a two-conductor transmission line are related by the following equations:

$$Z_c = \sqrt{\frac{z}{y}} \tag{88a}$$

$$\gamma = \sqrt{zy} \tag{88b}$$

where

$$z = r + j\omega l \tag{89a}$$
$$y = g + j\omega c \tag{89b}$$

The series inductance per unit length is l and the shunt capacitance per unit length is c.

If $r \ll \omega l$ and $g \ll \omega c$, then Z_c is very nearly a pure resistance

$$Z_c \doteq R_c$$

and γ is almost a pure imaginary

$$\gamma \doteq j\beta$$

Conversely, if the attenuation along the line is very small ($\alpha \ll \beta$), then

$$Z_c \doteq R_c$$

When a transmission line is terminated in an arbitrary impedance Z_a, the wave traveling down the line is reflected at this termination and travels back along the line with the same attenuation and phase constants as before. The ratio of the reflected voltage wave to the incident wave at the termination is called the voltage-reflection coefficient of the termination and is designated by Γ. Since the wave may undergo phase change as well as suffer attenuation on reflection, the reflection coefficient is a complex quantity. It is related to the terminating impedance by

$$\Gamma = \frac{Z - Z_c}{Z + Z_c} \tag{90}$$

The reflection coefficient for a terminating impedance equal to Z_c is zero; for an open-circuit termination $\Gamma = 1$ and for a short circuit $\Gamma = -1$. Any termination consisting of a pure reactance has a reflection coefficient whose magnitude is unity if the attenuation constant of the transmission line is small ($\alpha \ll \beta$; therefore $Z_c = R_c$).

It is convenient to normalize the terminating impedance to the characteristic impedance of the line; thus

$$\frac{Z}{Z_c} = z_1 \tag{91}$$

In terms of the normalized impedance

$$\Gamma = \frac{z_1 - 1}{z_1 + 1} \tag{92}$$

When a voltage V_0 is impressed at the input terminals of a transmission line of length s terminated by an impedance with reflection coefficient Γ the voltage along this line is the sum of two waves—an incident wave

$$V_i(x,t) = V_0 e^{j\omega t - \gamma x} \tag{93}$$

traveling toward the termination and a reflected wave

$$V_r(x,t) = \Gamma V_0 e^{j\omega t - \gamma s} e^{-\gamma(s-x)} \tag{94}$$

traveling toward the generator. In using the voltage distribution on the line for determining the impedance of the termination it is convenient to express this voltage in terms of w, the distance from the termination to the point under investigation. Then

$$w = s - x$$

and the voltage on the line is

$$V(w,t) = V_0 e^{j\omega t - \gamma s}(e^{\gamma w} + \Gamma e^{-\gamma w}) \tag{95}$$

The ratio of reflected voltage to incident voltage at any point w corresponds to an apparent coefficient of reflection at the point w of

$$\Gamma(w) = \Gamma e^{-2\gamma w} \tag{96}$$

The apparent normalized impedance of the termination as seen from the point w is therefore

$$z_1(w) = \frac{1 + \Gamma(w)}{1 - \Gamma(w)} = \frac{1 + \Gamma e^{-2\gamma w}}{1 - \Gamma e^{-2\gamma w}} \tag{97}$$

Equations (95), (96), and (97) take on a much simpler form and computations involving their use can be carried out more conveniently if the voltage-reflection coefficient is expressed as a complex exponential:

$$\Gamma = e^{-2\theta} \tag{98}$$

where

$$\theta = \rho + j\Phi \tag{99}$$

The quantity θ is called the *complex terminal function*, its real part is called the *attenuation function*, and its imaginary part is called the *phase function*.

Using this notation Eq. (95) becomes

$$V(w,t) = 2V_0 e^{j\omega t - (\theta + \gamma s)} \cosh(\theta + \gamma w) \tag{100}$$

and Eq. (97) becomes

$$Z_1(w) = \coth(\theta + \gamma w) \tag{101}$$

The normalized impedance of the termination is

$$Z_1 = \coth \theta \tag{102}$$

Both the real and imaginary parts of the terminal function θ can be determined from the magnitude of the voltage distribution, and the normalized impedance can then be computed from Eq. (102). The phase function Φ can be found from the position of a minimum or a maximum on the measuring line. From Eq. (100) the magnitude of the voltage on the line is

$$|V|^2 = 4V_0^2 e^{-2(\rho + \alpha s)}[\cos^2(\Phi + \beta w) + \sinh^2(\rho + \alpha w)] \tag{103}$$

The attenuation on a good measuring line is very low and under this condition the minimums of $|V|^2$ occur at

$$\Phi = (2n + 1)\frac{\pi}{2} - \beta w_{\min} \tag{104}$$

and the maximums occur at

$$\Phi = n\pi - \beta w_{\min} \tag{105}$$

where n is an integer.

A measurement of the distance to a minimum or a maximum thus permits Φ to be determined. The position of a minimum is almost always used since it can be located much more accurately than can a maximum.

There are two common methods for determining the attenuation function. One is the *standing-wave-ratio method* and the other is the *curve-width method.* In the standing-wave-ratio method ρ is determined from the standing-wave ratio, which is defined as the ratio of a maximum to a minimum of the voltage distribution.

$$S = \frac{|V|_{\max}}{|V|_{\min}} \tag{106}$$

Substitution of the conditions for a maximum and minimum from Eqs. (104) and (105) into Eq. (103) and taking the square root of the ratio yield

$$S = \coth\,(\rho + \alpha w_{\min}) \tag{107}$$

where $w_{\min}$ is the distance from the termination to the position of the minimum and where the difference in attenuation between the position of the maximum and the position of the minimum is neglected. The quantity $\alpha w_{\min}$ is also usually negligible in comparison with ρ, but this quantity can be measured and taken into account if required. The attenuation function ρ can be found from S by means of Eq. (107).

In the curve-width method ρ is determined from the distance between two points on either side of a minimum where the magnitude of the voltage has risen to p times the minimum value. When the ratio

$$\frac{|V|^2}{|V|_{\min}^2} = p^2 \tag{108}$$

is formed from Eq. (103) the following result is obtained:

$$(p^2 - 1)\sinh^2\,(\rho + \alpha w_{\min}) = \sin^2\frac{\beta\delta}{2} \tag{109}$$

where δ is the distance from the point where $\dfrac{|V|}{|V|_{\min}} = p$ on the other side (Fig. 66). The ratio $p = 2$ is usually chosen, in which case

$$\sinh\,(\rho + \alpha w_{\min}) = \sin\frac{\beta\delta}{2} \tag{110}$$

For standing-wave ratios greater than 10 the hyperbolic and the trigonometric sines in Eq. (110) are approximately equal to their arguments and

$$\alpha w_{\min} \doteq \frac{\beta\delta}{2} \tag{111}$$

Under this restriction

$$S \doteq \frac{2}{\beta\delta} = \frac{\lambda}{\pi\delta} \tag{112}$$

The standing-wave-ratio method is almost always used when the standing-wave ratio is less than 10. The curve-width method is preferable for standing-wave ratios greater than 10.

53. Standing-wave-ratio and Impedance Measurements. The measuring line used for making standing-wave and impedance measurements consists of a section of transmission line with an axial slot through which a small probe projects. This probe is arranged so that it can be moved along the line while its depth of projection into the slot remains constant. A scale attached to the line permits the position of the probe

to be determined. A signal source is connected to one end of the line and the termination whose impedance is to be measured is connected to the other. The voltage distribution on the line is determined by observing the output of a detector connected to the probe as the probe is moved (Fig. 67).
FIG. 67. Block diagram of measuring line and associated equipment.

The standing-wave ratio can be measured directly and the terminal functions ρ and Φ from which the impedance is computed can be easily determined from the voltage distribution.

a. Determination of the Phase Function Φ. The phase function is determined as follows:

1. Place a short circuit at the terminal end of the line.

2. Locate two adjacent minimums on the slotted section—preferably the first and second from the termination. The distance between these two minimums is $\lambda/2$:

$$\lambda = 2(w_{sc2} - w_{sc1}) \tag{113}$$

and each of the minimums is an integral number of half wavelengths from the termination. Since the scale may not be zero at the termination the position of one of the short-circuit minimums serves to locate the termination with respect to the scale.

3. Remove the short circuit and connect the unknown termination in its place.

4. Find the position of the new minimum nearest any one of the short-circuit minimums. The new minimum must be less than $\lambda/4$ from the reference short-circuit minimum. Then

$$\Phi = \frac{\pi}{2} + \frac{2\pi}{\lambda}(w_{sc} - w') \tag{114}$$

where w_{sc} = position of reference short-circuit minimum
w' = position of minimum with unknown termination

b. Standing-wave-ratio Method of Determining Attenuation Function ρ. The detectors used in making slotted-line measurements are usually crystals or bolometers and the detected output is proportional to the square of the voltage on the line. A linear detector or one following any other law may be used but the detection law must be known.

The procedure for determining the standing-wave ratio is as follows:

1. With the unknown termination connected to the slotted section, set the probe to the position of a minimum and adjust the detector and signal source power so that the detector output is well above the noise level.

2. Read the detector output.

3. Without changing the gain of the detector or signal generator output setting, move the probe to the position of a maximum and read the detector output. The maximums are

broad so that the exact position of a maximum is difficult to determine but the maximum value of the detector output as the probe is moved along the line can be determined easily.

4. The voltage standing-wave ratio

$$S = \frac{|V|_{max}}{|V|_{min}} \tag{106}$$

If a square-law detector is used

$$S = \sqrt{\frac{\text{maximum detector output (step 3)}}{\text{minimum detector output (step 2)}}}$$

If a linear detector is used

$$S = \frac{\text{maximum detector output (step 3)}}{\text{minimum detector output (step 3)}}$$

The terminal function ρ can be determined from the relation

$$S = \coth (\rho + \alpha w_{min}) \tag{107}$$

where w_{min} is the distance from the minimum used to the termination. The quantity αw_{min} can usually be neglected so that

$$S \doteq \coth \rho \tag{115}$$

The chief source of error in this method of determining ρ is the accuracy of the detector. In crystal detectors the detection law changes with signal level and becomes linear at large signal levels. It is therefore necessary to calibrate the detector if high standing-wave ratios are to be measured or if extreme accuracy is desired. Bolometer detectors follow the square law much more accurately than do crystals but are usually less sensitive and require more power from the signal source.

c. Curve-width Method of Determining the Terminal Function ρ

1. With the unknown termination connected to the slotted section set the probe to the position of a minimum and adjust the detector and signal-source power so that the detector output is well above the noise level.

2. Locate the two points on each side of the minimum where the voltage is 1.41 times the minimum value. When a square-law detector is used the detector output is double the minimum value at these points. Record the distance δ between these points.

3. Repeat steps 1 and 2 with a short circuit in place of the unknown termination and again record the distance δ'.

4. For standing-wave ratios greater than 10

$$\rho \doteq \frac{\pi(\delta - \delta')}{\lambda} \tag{116}$$

and

$$S \doteq \frac{1}{\rho} \tag{117}$$

This method is usually more accurate for standing-wave ratios greater than 10 than is the standing-wave-ratio method. However, the accuracy is dependent upon the accuracy with which the two points at which the voltage is 1.41 times the minimum value can be located. The accuracy can be improved if the voltage at 8 or 10 points in the vicinity of a minimum is measured and the voltage distribution is plotted on paper. The width between the 1.41 voltage points can then be determined from this plot.

54. The Measuring Line. The measuring line usually consists of a section of coaxial line with an axial slot through which a small movable probe projects (Fig. 68). Although this piece of equipment is basically very simple, the accuracy of the measurements made through its use depends to a large extent on the design of the line and the precision with which it is constructed.

In designing a measuring line, or in choosing one from those commercially available, the following factors should be considered:

1. The line should be of rigid mechanical construction and should have extremely low losses. Preferably it should have air dielectric and the slot should be narrow to prevent radiation losses.
2. The characteristic impedance should be constant along its length. This means that the cross section of the line should be constant along its length and the inner conductor should be accurately centered. The value of characteristic impedance chosen is arbitrary, and it is usually convenient to make this impedance equal to the characteristic impedance of the coaxial power-transmission cables with which the measuring line is usually used.
3. Mechanical tolerances permitted in maintaining constant characteristic impedance and in keeping the probe coupling constant are less severe on large lines. However, the diameter of the line must be small enough so that all modes except the *TEM* mode are suppressed at the highest frequency for which the line is to be used.
4. Supports for the center conductor should be designed so that reflections from them are negligible. Dielectric supports within the slotted section should be axially continuous along the length of the slot. A wedge-shaped support of this type is satisfactory (Fig. 68*b*), or the inner conductor can be left unsupported through the slotted region if it is sufficiently rigid, in which case the dielectric supports at the ends can be undercut to
FIG. 68. Measuring line and cross-sectional view.

minimize reflections. Foam-polystyrene supports, which cause only slight reflections, are often used.

5. The tapered transition section and connector by which the measuring line is connected to coaxial cables normally used for power transmission at these frequencies should be designed to have negligibly small reflections.
6. The probe carriage should be designed so that the depth of penetration of the probe into the slot is kept constant as the probe is moved along the line. Changes in probe depth and the resultant changes in coupling to the line cause inaccuracies when low standing-wave ratios are measured and they limit the minimum VSWR which can be obtained. Small circumferential movements of the probe also change the probe coupling. Tolerances on circumferential motion are not so severe as those for radial motion and the errors caused by circumferential motion can be reduced by extending the coaxial shield around the probe through the wall of the outer conductor of the line (Fig. 68*b*).

The variation of the coupling of the probe to the line as the probe is moved axially can be measured by means of an audio-frequency signal. In this test an a-f generator is connected to the line with an open-circuit termination on the load end and the output of the probe (without detector) is monitored with a VTVM after amplification in a high-gain audio amplifier. The wavelength at audio frequencies is so long that the voltage distribution on the line is constant and any changes in the output of the amplifier as the probe is moved are due to changes in coupling.

An alternative configuration (Fig. 69) often used for a measuring line has a cylindrical inner conductor and an outer conductor consisting of two parallel flat plates. Although the slot is wide it is in a region of low electric field and radiation losses are low. This line has the advantage that the probe is in a region of low field and that the

probe penetration is large for the desired coupling. Small changes in probe depth therefore have negligible effect on the coupling. The design of transition sections for connecting the measuring line to coaxial cables poses a problem, but lines of this type are commercially available in which the reflections from the transition section are extremely low.

Fig. 69. Parallel-plate line.

55. Signal Generators and Detectors. Any oscillator or signal generator which will operate at the desired frequency and which will furnish sufficient power to give a signal about 10 db above the detector noise at the minimum of the voltage distribution can be used as a signal source for transmission-line measurements. The harmonic output of the signal source should be low and it is advisable to put a low-loss filter, with a cutoff frequency between the fundamental and second harmonic, in the output line to ensure low harmonic content, particularly if high standing-wave ratios are to be measured. It is usually convenient to use an r-f signal modulated with an audio tone.

The most common type of detector consists of a crystal or a bolometer to detect the audio modulation followed by a high-gain narrow-band audio amplifier. Some tuning device such as a double-stub tuner is usually necessary to obtain sufficient sensitivity. Often the bolometer or crystal holder and associated tuning device are built into the probe carriage. The output from the audio amplifier can be measured with a VTVM. Audio amplifiers with built-in voltmeters designed specifically for transmission-line measurements are commercially available.

A microammeter can be used with a crystal detector to measure the rectified crystal current and thus indicate the voltage on the line. This system is not very sensitive and requires more power from the signal source than does the crystal and audio amplifier. A superheterodyne receiver makes an excellent detector but the high sensitivity of this instrument is not usually needed and the comparatively simple crystal or bolometer with audio amplifier is more convenient to use.

The detection law must be known to measure the VSWR. In this respect bolometers are superior to crystals. The detected output from a bolometer is usually proportional to the square of the input signal over a wide range of input signal levels ($\sim$30:1). A crystal is only approximately a square-law detector and the detected output can be assumed proportional to the square of the input signal with reasonable accuracy only over an input range of 3 or 4 to 1. A crystal, however, is usually more sensitive than a bolometer.

Fig. 70. Use of voltage distribution for detector calibration.

The detector can be calibrated by means of the current distribution on the slotted section of transmission line when the line is terminated in a short circuit. The distribution of current on a short-circuited line is sinusoidal with high accuracy except in the regions very near the minimums.

The procedure for calibration is as follows (Fig. 70):

1. Locate two adjacent minimums on the line. The distance between these minimums is $\lambda/2$.
2. Find the point A halfway between these two minimums; all distances x are to be measured from this point.
3. Set the probe at point A and adjust the input signal level (signal source) until the output from the detector is the maximum needed for measurements. Designate the voltage at point A by V.
4. Move the probe (in either direction) in equal increments of cos $(2\pi x/\lambda)$ until

$$\cos \frac{2\pi x}{\lambda} = \tfrac{1}{2}$$
($x/\lambda = 1/6$) and record the output voltage for each probe setting. The input voltages are given by

$$V_i = V \cos \frac{2\pi x}{\lambda}$$

5. Set the probe at point A again and adjust the input signal until the output is the same as it was with the probe set at $x/\lambda = 1/6$ in step 4. The input voltage at point A is now $V/2$ and the voltage distribution is $V_i = V/2 \cos (2\pi x/\lambda)$.

6. Repeat steps 4 and 5 until the signal decreases to the detector noise level, or as far as is desired.
FIG. 71. Transmission-line charts. (a) r_1-X_1 chart; (b) Smith chart.

56. Transmission-line Charts.[18] Several types of diagram are in common use for graphical solution of transmission-line problems. Graphical solution is much faster than numerical solution of the equations, and although it does not afford as high accuracy, the accuracy is sufficient for most computations.
FIG. 72. Use of the Smith chart. (*a*) Voltage distribution; (*b*) graphical computation of impedance.

One of the simplest charts is that shown in Fig. 71*a*. It consists of a rectangular coordinate system in which one coordinate is the real part and the other the imaginary part of the normalized impedance $z_1 = Z/Z_c$. Only the right half plane is needed since negative values or r_1 are not encountered (assuming Z_c real). Superimposed on this coordinate system are lines of constant magnitude of the reflection coefficient and lines of constant phase angle of the reflection coefficient. From Eqs. (96) and (98)

the apparent reflection coefficient at any point on a line is

$$\Gamma_{(w)} = \Gamma e^{-2\alpha w} e^{-2j\beta w} \tag{118a}$$
$$\Gamma_{(w)} = e^{-2(\rho+\alpha w)} e^{-2j(\Phi+\beta w)} \tag{118b}$$

where Γ is the reflection coefficient at the load. Therefore, moving along a line of constant $|\Gamma|$ on the chart corresponds to moving along a lossless transmission line and the distance moved determines the change in the angle βw. The lines of constant $|\Gamma|$ are also lines of constant VSWR,

$$S = \frac{1 + |\Gamma|}{1 - |\Gamma|} \tag{119}$$

and are usually marked directly in S.
FIG. 73. Smith chart.

The Smith chart[19] (Fig. 71*b*) is the most widely used transmission-line chart and is probably the most convenient diagram to use. It is, in effect, the chart of Fig. 71*a* rolled up so that the whole right half plane of the r_1-x_1 coordinate system is contained in a unit circle. The lines of constant r_1 and lines of constant x_1 are plotted on a polar coordinate system in which the radial coordinate is $|\Gamma|$ and the angular coordinate is the phase angle of Γ.

Transforming an impedance through a section of lossless transmission line, therefore, consists of moving around the chart at constant radius. Lines of constant VSWR are circles of constant radius (usually not drawn on the diagram) and the value of r_1 at which one of these circles crosses the positive real axis is the value of S for the circle. The value of r_1 at which it crosses the negative real Γ axis is $1/S$. The angular coordinate is $2(\Phi + \beta w)$ as can be seen from Eq. (118b) and it is usually marked directly in w/λ so that the length of line (in wavelengths) through which a transformation is made can be read directly from the chart.

As an example of the use of the Smith chart, suppose that the voltage distribution on a measuring line is as shown in Fig. 72a and the impedance of the termination is to be computed. The wavelength on the line is found from the distance between the two adjacent short-circuit minimums to be 50 cm and the distance from the short-circuit minimum at B to the minimum on the voltage distribution for the unknown impedance at A is $\Delta w = 8.13$ cm. The VSWR for the unknown termination is 2.6:1. Enter the chart at point A (Fig. 72b) which corresponds to a voltage minimum on a 2.6:1 VSWR distribution. Move counterclockwise around the chart (toward load) on the 2.6:1 circle through an angle $2\beta\,\Delta w = 4\pi\,\Delta w/\lambda$. This angle can be found by locating the point $\Delta w/\lambda$ on the scale along the circumference of the chart. Since $\Delta w/\lambda = 0.1626$ the new point is at B. The value of

$$z_1 = r_1 + jx_1$$

as read from the chart at point B is the normalized impedance of the termination. In this case it is $r_1 = 1 - j$. The actual impedance of the termination is

$$Z = R_c(r_1 + jx_1)$$

It should be noted that, if the short-circuit minimum at point C is used as a reference, then the 2.6:1 circle is traversed in the clockwise direction (toward the generator) for a distance corresponding to $\Delta w/\lambda = 0.3374$ which again leads to point B.

CHAPTER 15

AUDIO-FREQUENCY AMPLIFIERS

By Richard C. Hitchcock[1]

GENERAL REQUIREMENTS

1. General. The term audio includes some or all of the frequencies from 20 to 20,000 cps. This range contains practically all the fundamentals and most of the harmonics of speech and music. The term audio applies equally well to acoustic waves and to electrical impulses. An audio (a-f) amplifier utilizes low-energy electrical frequencies at its input and delivers the same frequencies at higher energy at its output. An input transducer is usually required to provide appropriate electrical impulses. Typical transducers are microphones, phonograph pickups, tape-head pickups, and radio detectors. At the output, another transducer is needed such as a loud-speaker or headphone to change the amplified electrical impulses into acoustic energy.

2. Voltage and Power Gain. A multistage tube amplifier consists of voltage amplifiers at the input, utilizing high-gain tubes such as triodes or pentodes, and of power amplifiers at the output stage utilizing low-impedance triodes or beam-power tubes. The individual stages are usually *RC*-coupled to each other, although transformers are often employed for this purpose. The power stage is coupled to the output transducer by means of an impedance-matching transformer. Some special circuits are available which make this output transformer unnecessary (Sec. 49).

Single-tube outputs are usually operated as class A, push-pull stages as class AB_1 or class B.[2] Class B amplifiers have high efficiency, delivering relatively high audio output per watt of d-c power input. The d-c power for all amplifiers is usually supplied by a combination of transformer, rectifier, and filter.

3. Design Parameters. The following items are important in choosing or designing an a-f amplifier, the numbers referring to sections that follow:

4. Output power needed
5. Input available
6. Range of frequencies desired, or needed
7. Distortion allowable
8. Stability
9. Power supply
10. Cost
11. Space
12. Service

[1] Syntron Company, Homer City, Pa.

[2] A class A amplifier operates in such a manner that the output wave form for a single tube and any kind of output impedance is substantially the same as the input wave form. Plate current flows for the full 360 electrical degrees of the input emf. When the grid of a class A amplifier is not driven positive with respect to the cathode, it is designated as class A_1. When the grid is driven positive, it is designated as class A_2. Class A_2 is seldom used because of high plate losses. Hence class A usually means that the grid is not driven positive.

A class AB amplifier is operated with sufficient grid bias for a given d-c plate potential that plate current flows for more than 180 deg but less than 360 deg of the input emf. This mode of operation requires two tubes in push-pull in order that the output wave form be nearly like the input wave form. When the grids of the tubes are not driven positive with respect to the cathodes, the designation is class AB_1. When the grids are driven positive, the designation is class AB_2.

A class B amplifier is operated with sufficient grid bias to reduce the plate current almost to zero when no input voltage is applied. Plate current flows for only 180 deg of the input cycle. It requires two tubes in push-pull to produce an output wave form that is nearly like the input wave form.

4. Output Power Required. A few milliwatts of electrical output power is sufficient for hearing aids or personal portable radios; for table radios, television sets, or tape recorders from ½ to 2 watts is necessary. For home high-fidelity sets, 10 to 20 watts is common. Amplifiers with rated outputs over 20 watts are used in industrial plants, theaters, hotels, hospitals, and the like.

To measure the electrical output power from an audio amplifier is relatively straightforward. But this is seldom a complete answer to a given application because a loud-speaker is needed to change the electrical watts to acoustic watts. The needed factor, the efficiency, is the ratio of the acoustic watts to the electrical watts. Unfortunately this cannot be specified for the complete audible spectrum, nor is the human ear equally sensitive to all frequencies. The variation in ear sensitivity is detailed by the Fletcher-Munson curves.[1] Furthermore a given loud-speaker unit, when used in various enclosures, may range in efficiency over a range of 10 to 1.

As approximate working figures, *the acoustic power* required for a small apartment is about 2 watts, for a large living room 4 watts, for a small auditorium 8 watts. For
FIG. 1. Indoor acoustic power requirements. (*From Western Electric.*)
FIG. 2. Outdoor power requirements for speech. (*From Western Electric.*)

home use it is always possible to "turn it down," and so extra electrical power or more efficient speakers may be employed. However, for a multispeaker system, such as for industry, it is essential that as much planning go into the system as possible to ensure its adequacy.

As a rough guide, a loud-speaker mounted on a flat baffle, or in an open-backed box, has an efficiency of 5 per cent; in a closed padded box 10 per cent; in a bass-reflex cabinet 20 per cent; and in an exponential horn, up to 40 per cent. Small exponential horns are used for speech reinforcement and public-address work, although their frequency response is limited. Their efficiencies in the speech range may be as high as 25 per cent. Some commercial speaker enclosures exchange efficiency for smooth and wide-range response. One such device[2] has an acoustic efficiency of 1 per cent but it has only 1.7 cu ft inside volume.

The output power of electrical energy needed, therefore, depends on both the speaker efficiency and the space to be supplied with acoustic energy. A 20-watt amplifier with a 5 per cent efficient speaker will supply 1 watt of acoustic energy. This is somewhat low for high fidelity. A 20-watt amplifier with 25 per cent efficient

See Chap. 1, Fig. 10, or Chap. 11, Fig. 8, of this handbook.

[2] Acoustic Research AR-1 speaker system.

small horns will put out 5 watts of acoustic energy (with restricted bass response), enough for a space 100,000 cu ft, according to Fig. 1.

The chart in Fig. 1 shows the acoustic watts required for indoor enclosures from 1,000 to 10,000,000 cu ft, both for public-address speech, and (multiplied by 10) for the maximum needed for concert music. For outdoor work, Fig. 2 shows the acoustic watts for 10 to 10,000 ft distance, over an angle of 30 deg. Multiple speakers are needed if the angle is greater than this.

As a rule, the loud-speaker load is closely matched to the amplifier output impedance. This is essential for maximum fidelity and power output. However, for public-address and similar work, it is often close enough to use transducer loads from 75 to 125 per cent of the amplifier rated output impedance.[1]
FIG. 3. Microphone ratings. *A-B*, typical high-impedance; *C-D*, low-impedance.

5. Inputs Required. In Table 1 typical ranges of output rms volts and load impedance are listed. Further mention of the transducers noted there will be made below.

Microphones. Microphone ratings are shown in Fig. 3.[2] Scale 3 is the sound-voltage rating ordinarily specified for high-impedance microphones. An example will illustrate the use of these data.

A dynamic moving-coil microphone with its built-in stepup transformer is rated at -60 db sound voltage, scale 3. This is enough information to find the desired microphone voltage on scale 2, but to show the relationship to sound power, draw dashed line *A* to the nominal impedance, scale 5, at 25,000 ohms. This microphone has a -60 db sound-power rating on scale 4, where 0 db is 1 mw per 10 microbars (10 dynes/cm^2). Line up -60 db sound voltage, scale 3, with the sound-pressure level 60 db on scale 1, showing the microphone, output voltage of 200 μv on scale 2, dashed line *B*.

This microphone also has an optional low-impedance connection of 150 ohms, scale 5, with -60 db sound power, scale 4. Dotted line *C* intersects scale 3 at -82 db sound voltage; this intersection is aligned, using dotted line *D*, with the same initial sound-pressure level on scale 1, to show a microphone voltage of 16 μv on scale 2. For scale 3 values below 100 μv a stepup transformer is used, either built into the case or connected at the end of a

low-impedance shielded microphone line. Low-impedance microphone lines are desirable since pickup of extraneous signals is minimized, and the high frequencies are attenuated less owing to cable capacitance.

Table 1. Input Transducers

	Output, volts rms	Load impedance, ohms
Ceramic and crystal phono pickups	0.5–2.0	500,000–3,000,000
Reluctance (magnetic) phono pickups	0.005–0.05	10,000–50,000
Microphones, high-impedance	0.0002–0.02	25,000–100,000
Tape-head pickups	0.005–0.01	200–3,000
Vibration pickups	Various	Various
Radio and TV detectors	0.5–5.0	50,000–500,000

Crystal microphones invariably are high-impedance, 25,000 to 50,000 ohms being common. Some microphones have an adjustable response to accentuate the higher-frequency consonants in speech sounds, as much as 10 db.[1] By exposing both surfaces of the diaphragm, the response of another microphone type is better to close-up sounds than to far-away sounds.[2]

Phonograph Pickups, Tape-head Pickups. These will be treated in more detail in Sec. 17.

Vibration and Noise Pickups. Sound-level meters and vibration pickups are a specialized field, and several commercial devices are available.[3] The signal for which an analysis is desired may be, for example, a noise, a complex musical sound, or a mechanical vibration.[4] An analyzer is usually a combination of a filtering system, an amplifier, an attenuator, and an indicating meter. Often these units are combined in a single unit that cannot be tested or rated separately.

Pressure transducers of barium titanate are[5] available with ranges of 0.5 to 30,000 cps flat to ±2 db and with sensitivities of −101 db referred to 1 volt per microbar. These will withstand static pressures of 5,000 psi and operate at −20 to 90°C.

One vibration meter[6] is battery-powered, transistor-operated, etched-circuit-wired, and has a sensitivity of 0.005 in. peak to peak, giving full-scale deflection from 50 to 1,000 cps and usable down to 10 cps.

6. Frequency Range. For pleasing reproduction of music it is an experimental fact that the upper and the lower range of frequencies have a definite relation.[7] If all frequencies are equally amplified and reproduced, the top and bottom frequencies multiplied together should give a figure between 400,000 and 500,000. Taking the lowest figure, 400,000, three systems may be mentioned: fair, 80 to 5,000 cps, 6 octaves; good, 40 to 10,000 cps, 8 octaves; and excellent, 20 to 20,000 cps, 10 octaves. The "fair" system is characteristic of ordinary home radio receivers and phonographs.[8]

The over-all frequency response of speech-reinforcing systems covers only a restricted range[9] but should be at least from 400 to 4,000 cps, and preferably one octave

further at each end, or from 200 to 7,000 cps for auditoriums of 237,000 to 5,000,000 cu ft.[1]

Interesting experiments are being performed to show how much speech can be compressed either as a function of frequency range or in the total time required to present it, but these tests are not considered here.[2]

7. Allowable Distortion. All amplifiers have distortion, that is, they are not true linear devices. The important matter is to determine what kind and how much distortion can be permitted for a given application. The requirements placed on an amplifier for a restricted-range small radio receiver are altogether different from those needed in a home-type high-fidelity system.
FIG. 4. Audio-frequency ranges required for various types of service.

In general, amplifier distortion is of two kinds. One type is harmonic distortion produced by nonlinearity and composed of higher harmonics of the input voltage. The other type, known as intermodulation distortion (IMD), is evidenced by the modulation of one frequency by another and by the production of sum and difference frequencies not present in the input to the amplifier. IMD is considered as the more important in high-quality systems. Table 2 gives an indication of the values of frequency range, power output, and distortion likely to be found in several audio systems.

Table 2. Typical Audio Amplifiers

	Range, cps	Output power, watts	Total harmonic distortion, %
Telephone:			
Commercial	200–3,000	0.006	
Permanent and temporary AM broadcast, schedule A	50–5,000	0.006	
FM broadcast and TV audio	50–8,000	0.006	
FM broadcast, schedule AA (less frequently used)	50–15,000	0.006	
Portable radios, tubes, and transistors	200–4,000	0.03–0.15	10
Table radio, table TV, portable phono	150–4,500	0.5–2.0	10
Console radio, console TV	70–7,000	2–10	10
Apartment, medium-fidelity phono	50–15,000	2–5	5
High-fidelity phono, large room	20–20,000	10–20	2
High-fidelity phono, auditorium	20–20,000	20–50	2
Public address, speech	300–5,000	10–100	5–10
For reference:			
Human-ear range, average all ages	20–10,000		
Young and exceptional ears	20–20,000		
Standard 88-note piano, fundamentals (A_0 = 27.5; middle C_4 = 261.3; A_4 = 440; C_8 = 4,186)	27.5–4,186		

It has been demonstrated that 5 per cent IMD is too much for a high-quality system, that 2 per cent can be detected by a keen ear. As little as 1 per cent is attainable by good design.[1]

8. Stability. A new amplifier should be tested by using an oscilloscope across the output, to see if inaudible frequencies are present. It is possible for an amplifier completely quiet to the ear to have, say, a 50,000-cycle oscillation, which may overload the output tubes and thus cause poor quality in the audible range.[2]

9. Power Supply. Usually a conventional transformer-rectifier-filter system supplies the d.c. for plates, screen grids, and bias voltages; see Fig. 25. Tube heaters are usually run on a.c., though for high-gain input stages, d.c. is desirable to decrease hum.

For portable work, battery-type tubes with low current drain are necessary. The transistor is excellent for this application. Transistors have no filament power to furnish, but they have at least one complicating difference from vacuum tubes—their inputs and outputs are interdependent, requiring care in design.

10. Cost. Some idea of relative cost may be obtained by considering the various types of components involved in an audio amplifier. The output transformer, when called on to reproduce 8 or 10 octaves, with minimum distortion and faithful response, is the most expensive component. This is one reason for designing amplifiers which do not require an output transformer (see Sec. 49). Beam-power tubes handle more power than triodes or triode-connected pentodes, and to keep costs down beam pentodes are attractive. Good interstage and input transformers are not cheap, though not so expensive as the output transformer because of their lower level of operation. Many amplifiers use resistors and capacitors, some with high-gain pentode tubes, to eliminate the interstage transformers. Microphones with low impedances require a stepup transformer, as mentioned in Sec. 5.

Practically all power amplifiers use a power transformer. An alternative is to connect the heaters of the tubes in series and to connect the "string" across the power line. The warm-up times of the tubes should be equal. Some plate-voltage sources use doublers (Sec. 48). Both these methods will eliminate the need for a power transformer but they add the hazard of line voltage appearing on the metal chassis. To avoid this trouble an isolation transformer between the device and the power

[1] Hitchcock, R. C., Intermodulation Distortion, *Audio Eng.*, **36**, 21, October, 1952. Jones, E. M., How Much Distortion Can You Hear? *Trans. IRE (Audio)*, **AU-2**, 42, March–April, 1954.

[2] Hitchcock, R. C., Testing with White Sound, *Audio*, **38**, 41, October, 1954.

line is sometimes employed but this puts back into the device the costs saved in eliminating the power transformer.

11. Heat Dissipation. A power amplifier must be able to get rid of some of its heat. It is seldom advisable to enclose a power amplifier completely; air circulation must be provided. Amplifier chassis usually have louvers which indicate where such circulation is expected.

12. Service. From time to time, tubes have to be removed for test or replacement. If an enclosure is used, some arrangement should allow tube removal with a minimum of trouble. Other components, which are moved often, such as volume controls, potentiometers, and switches, occasionally have to be replaced. The ready service of components should be designed into the amplifier. Some makers use the "one-layer" construction, so that each component can be reached once the chassis is removed from the cabinet. Others use a "layer-built" scheme. This requires the removal of one component to get at another beneath it.

Components potted in plastic cannot be separated; the complete assembly must be replaced. Printed circuits require special care when components are to be replaced.

13. Feedback. By principles which are now well known, a certain amount of voltage or current may be fed back into the input of an amplifier from the output in such phase as to subtract from the input voltage. By such negative feedback, the amount of distortion and noise produced by the amplifier may be reduced so that it does not appear in the loud-speaker. If the input voltage normally applied to the amplifier must be increased by a factor of 5 (14 db) to secure the same output power obtained without the negative feedback, the intermodulation distortion will decrease by a ratio of 5:1, approximately.

Thus, a 6L6 push-pull amplifier with no feedback will have approximately 5 per cent IMD at 5 watts output and when 14 db feedback (5:1 in voltage) is utilized, the IMD will be about 1 per cent.[1]

Negative feedback will decrease distortion, improve the transient stability, reduce noise, and slightly extend the frequency range. It will not increase the power output. It is most useful where the voltages applied to the amplifier are of the order of 1 volt or more.

In practice, some voltage or current is secured from the output of the amplifier and is applied to a point near the input, say to a single-ended driver stage. The feedback may be secured in parallel with or in series with the load by appropriate measures, sometimes by using a separate feedback winding on the output transformer, sometimes by a voltage-dropping resistor in series with the cathode-bias resistor of the stage to which the voltage is applied, and sometimes by taking the voltage drop across a low resistance in series with the loud-speaker. In the latter case it is known as current feedback and is particularly useful where the loud-speaker has an inadequate enclosure. Current feedback is seldom applied alone but is usually accompanied by some voltage feedback.

The feedback voltage may also be obtained from the primary of the output transformer by use of a resistor to lower the voltage and a capacitor in series to block the d-c voltage. Feedback obtained in this way may be usefully applied when the output transformer is not top quality because the feedback is not affected by leakage reactance.

14. Feedback Design. The principles involved may be readily ascertained by a typical calculation.

In Fig. 5 assume that a 9-ohm load is connected to the 9-ohm tap on the output transformer, that E_0 for 20.6 watts output is 13.6 volts. The input required e_i is 0.19 volt. Feedback is obtained by the voltage divider R-R_f, the portion appearing across R_f being applied across the cathode-bias resistor of the input tube.

Let E_f be the feedback voltage

$$E_f = E_0 R_f/(R + R_f) = 13.6 \times 470/4{,}070 = 1.57 \text{ volts}$$

[1] Hitchcock, R. C., Intermodulation Distortion, *Audio Eng.*, **36**, 21, October, 1952.

The total input voltage now required is

$$E_i = e_i + E_f = 0.19 + 1.57 = 1.76 \text{ volts}$$

Thus, with no feedback, 0.19 volt drives the amplifier to 20.6 watts output; with feedback 1.76 volts is required.

The feedback ratio $E_f/e_i = 1.57/0.19 = 8.26 = 18.3$ db.

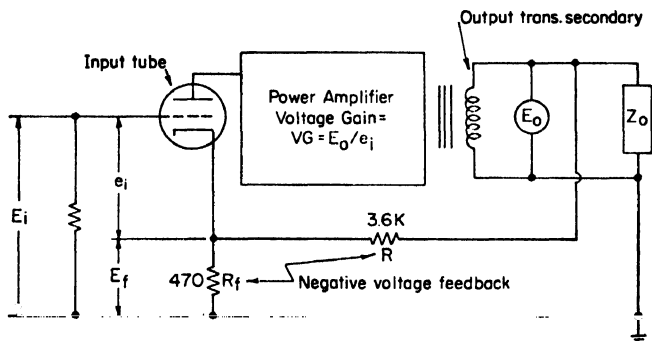
Feedback ratios of 5:1 to 10:1 (14 to 20 db) are customary.


FIG. 5. Feedback from output transformer secondary winding.

PREAMPLIFIERS

Because the output voltage of most transducers is very low, much less than 1 volt, considerable voltage amplification is necessary before the final power amplifier can be driven. In general this preliminary voltage amplification takes place in a separate unit called a preamplifier characterized by high gain and low noise and with whatever tone compensation is to be employed built into it.

The design of these amplifiers is straightforward. Descriptions of several types to follow illustrate the general arrangement.

15. Multiple-input Preamplifier. A preamplifier having five inputs, usable one at a time, designed for home-type high fidelity, is Fig. 6. There are three high-impedance inputs for tuner, television, and tape and two low-impedance inputs for magnetic pickups or microphone. At 1,000 cps for 1.5 volts output the high-level inputs require 0.075 volt, and the low-impedance inputs 0.0015 volt. Each high-level input has a potentiometer to preset the volume of incoming signals. Low-level circuits also have a volume control but effective after the signals have been amplified by the first dual triode. There is sufficient gain and equalization to play directly from a magnetic tape head, using the low-level magnetic pickup jack.

The two input tubes are operated at reduced voltage, and with d.c. on the heaters. The noise level is 95 db below 1.5 volts output. Two outputs, cathode-follower type, are provided.

Selector switches determine low-frequency turnover (bass boost compensation begins) and high-frequency rolloff (treble attenuation begins), with a total of 25 different positions. In addition the bass control can supply +13 db or −9 db at 100 cps, and the treble control at 5,000 cps can furnish +10 db or −9 db.

Plate current is supplied by two metal rectifiers and an *RC* filter, independent of the rectified heater supply also using metal rectifiers.

The tubes may be removed from the back without removing the chassis enclosure. Three power receptacles are energized by the on-off switch, for tuner main amplifier, phonograph motor, for example.

16. Single-input Preamplifier.[1] A preamplifier designed solely for magnetic pickups (Fig. 7) using two 6SJ7 pentode amplifiers and a 6SL7 double cathode follower provides 2 volts output. A voltage-regulator tube supplies a constant voltage needed for 40-db feedback. Any amplifier which has high gain at low frequencies is susceptible to "motor-

[1] Finlay, Alexander, A Simple—Yet Good Quality—Preamp, *Radio and Television News*, **52**, 42, November, 1954.

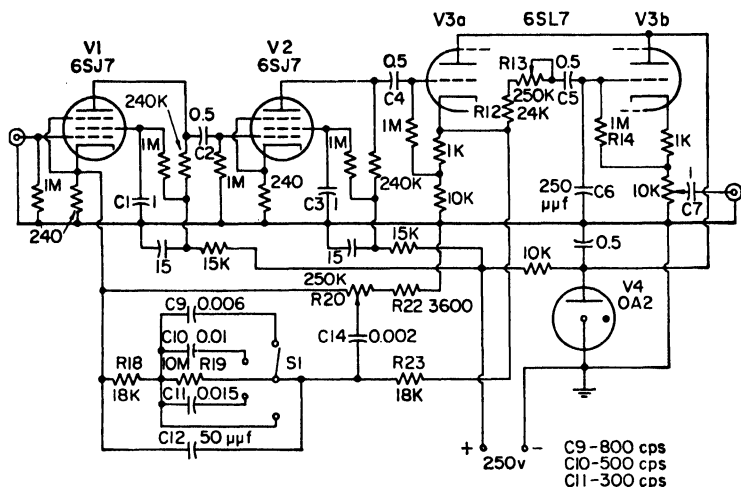
FIG. 6. Home-type high-fidelity preamplifier, Altec Lansing type 440B, with d.c. on heaters. Note the two controls for volume and loudness. The volume control attenuates all frequencies equally; the loudness control takes into account the Fletcher-Munson effect.
boating," and the use of the voltage-regulator tube isolates the cathode-follower plate circuits from the others. An external source of 250 volts d.c. and 6.3 volts a.c. is required. The 6SJ7 cathode resistors are lower than normal to obviate the need for bypass capacitors and allow maximum transconductance.


FIG. 7. Preamplifier for use with magnetic pickup.
FIG. 8. Preamplifier equalization curves.

The feedback loop comes from the first cathode follower by way of R_{23}, switch S_1 to the cathode of the input 6SJ7. This circuit shunts C_9, C_{10}, and C_{11} across R_{19}; the fourth switch point shunts C_{12} across R_{19} and R_{18} for the highest turnover frequency shown in Fig. 8. No bass boost is provided, but much the same effect can be obtained by increasing the turnover frequency. At 150-cps turnover, for example, the boost at 100 cps is 5 db, and with a 1,200-cps turnover, the boost at 100 cps is 22 db. Other turnover frequencies may

be obtained by using a series capacitor to replace C_9 in the feedback loop, with a value of $\frac{1}{4}\pi f_T R_{18}$, where f_T is the new turnover frequency and R_{18} is the 18,000 ohms (R_{18}) to the first 6SJ7 cathode.

A hum balancer across the heater winding, which puts 20 volts positive d.c. on the variable arm, will reduce hum. Substituting type 5693 tubes for the 6SJ7s makes this unnecessary. High-frequency rolloff is controlled in the output cathode follower V_{3b} grid circuit by R_{14}, C_6, and R_{13}. Different values may be obtained for a rolloff frequency f_R by changing R_{13} plus R_{12} to a value given by $\frac{1}{2}\pi f_R C_6$, where C_6 is 250 × 10^{-12} farad.

Treble boost is the R_{20}, R_{22}, C_{14} circuit from the first 6SJ7 cathode to ground. Set at mid-position, the response is flat; at one extreme of R_{20} half the feedback loop is shunted by C_{14}, giving a reduction of 6 db above 6,000 cycles. At the other extreme, there is an increase of amplification above 4,000 cycles.

Higher-value capacitors C_1, C_2, C_3, C_4, and C_5 contribute to the good low-frequency response. Tests showed sine-wave response from 1 to over 300,000 cps. Square-wave tests showed negligible tilt at 4 cps; at 1,200 cps there was no overshoot or ringing. Intermodulation distortion tests showed "no deflection of the meter on a 3 percent full-scale range."
FIG. 9. Characteristics of disk recording and playback.

17. Preamplifier Frequency Compensation. The frequency characteristics used during the recording of a phonograph disk determine what the response of the playback pickup must be to get uniform output for all frequencies. During recording, lateral velocities are limited more and more as the frequencies go lower and there is a limiting maximum lateral excursion of the stylus which will use the record space efficiently for both medium and low frequencies. At the other end of the spectrum, there is a preemphasis during recording, to improve the signal-to-noise ratio.

The "standard" commonly used by recording-disk manufacturers in the United States is the dashed line of Fig. 9. At 100 cps the relative velocity is −13.1 db, and at 10 kc it is +13.7 db.[1]

To counteract this characteristic the standard playback is the solid line of Fig. 9 which shows +12 db at 100 cps and −12 db at 10 kc.* The resultant is shown by the dot-dash line; +4 db at 30 cps, 0 db at 70 cps, 0 db at 1,000 cps, and +2 db at 8,000 cycles.

The object of a preamplifier compensation circuit is to provide this solid-line response, when using pickups on records, to feed an otherwise "flat" amplifier. Two such circuits are shown in Figs. 10 and 11.

A commercial preamplifier used for reluctance pickups is shown in Fig. 12. The output

[1] "New Orthophonic Recording Characteristics, RIAA Standard," RCA Record Division. Moyer, R. C., Evolution of a Recording Curve, *Audio Eng.*, **37**, 20, Fig. 4, July, 1953.

* AES Standard Playback Curve, *Audio Eng.*, **35**, 22, January, 1951.

is about 0.5 volt. The dotted input resistor R_1 can be any value from 6,800 to 58,000 ohms; the higher value gives better high-frequency response, but the pickup circuit will then be more susceptible to stray fields which may cause hum.

An inspection of the tone-control curves—Fig. 8 with maximum bass boost, and Fig. 8 with 340-cps turnover—will indicate that relatively flat response can be obtained with these controls without the need of added compensation. However, magnetic pickups have a low output voltage, in the range of 5 to 40 mv, and some amplification is required to reach the level where the tone control can be used.

A typical tape-head response is Fig. 13. This characteristic shows the same decreasing output with decreasing frequency as shown by the dotted line for disk records in Fig. 9. Note the position of 0 db at 200 cps for the tape head: it can be compared with the disk
FIG. 10. Triode equalization for standard disk recording.
FIG. 11. Pentode equalization for standard disk recording.
FIG. 12. Compensated preamplifier—General Electric UPX-003.
FIG. 13. Tape-head output. Brush Type BK-1090.

record by subtracting 8 db from the tape-head response. Thus the tape shows −18 db at 60 cps, compared with −13 db for the disk; at 1,000 cps the 7½-in.-per-sec tape has +5 db compared with 0 db for disk, and at 3,000 cps the tape is +7 db compared with +5 db for disk. Thus a 5-db bass boost at 60 cps is needed to compensate for the tape recording and still use the same compensation circuits shown for the disk.

18. Tone Controls. The use of a tone control is a controversial subject. It must be recognized that amplifiers, speakers, and input circuits are not perfect, and that the possibility of changing the frequency response may be justified. The simpler the controls, the better the adjustment to suit a particular situation. Inductor types of tone controls are seldom used at present; *RC* controls of the continuously variable type are favored. Two independent controls are customary: base controls affect the gain from 500 to 1,000 cps and below; treble controls, from 1,000 to 2,000 cps and above. The volume control is not a tone control.

A bass- and treble-control stage is shown in Fig. 14.[1] The two controls are poten-

[1] "RCA Receiving Tube Manual RC-17," June, 1955, p. 285.
FIG. 14. Circuit for bass and treble control.
FIG. 15. Feedback type of tone control. With 6SN7 instead of 6AU6, omit R_2 and C_1.
FIG. 16. Tone control available from circuit of Fig. 15.

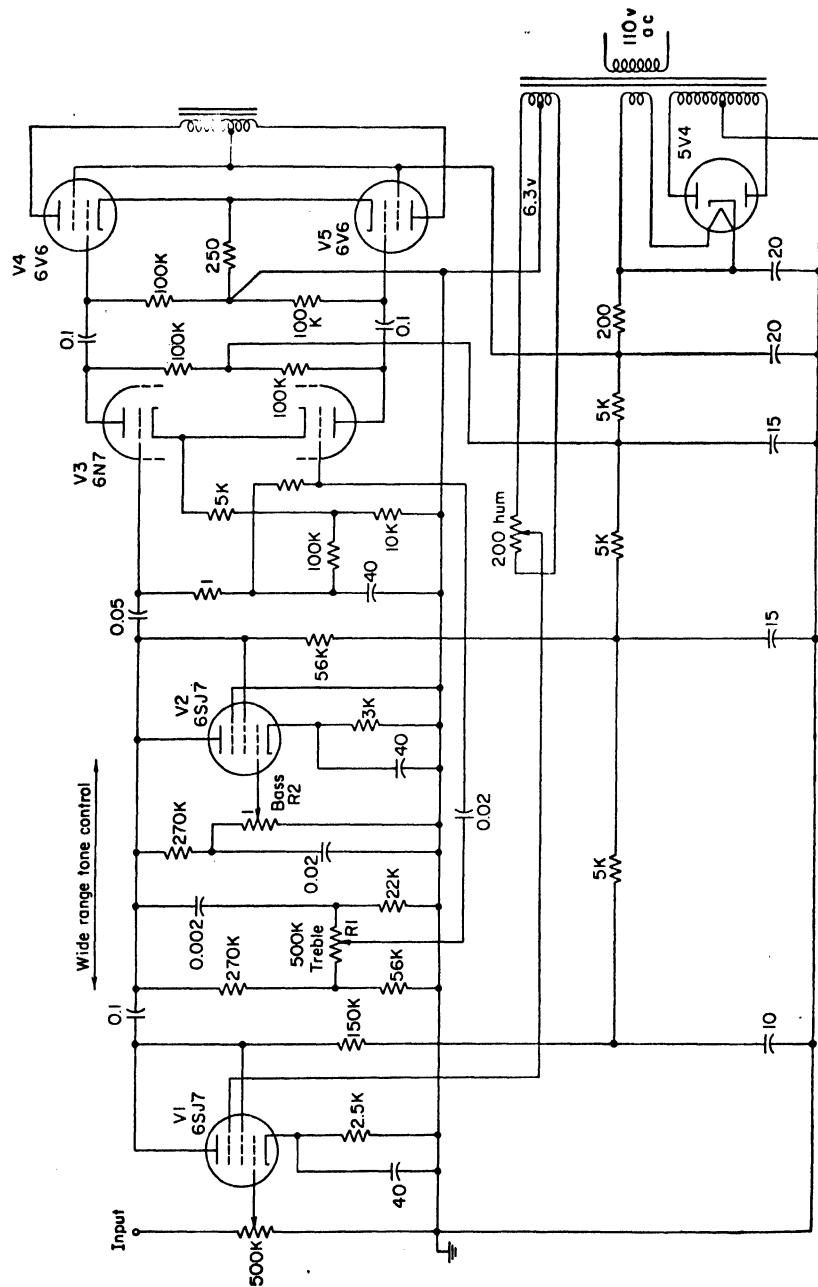
tiometers R_1 for treble and R_2 for bass, each with logarithmic taper. Boost is obtained as the potentiometer arms are moved "up" and cut as they are moved "down"; flat response is at the middle of the potentiometers. The curves are within 2 db of those shown in Fig. 16. There is no gain from V_1 but V_2 has a voltage amplification of about 10 so that the insertion loss of this circuit is practically zero.


Fig. 17. Wide-range 6-watt amplifier requiring 0.7-volt input.

A negative-feedback tone-control circuit is shown in Fig. 15. Treble control R_1 is a linear potentiometer. Bass control R_3 gives neither boost nor cut at its center. The circuit was originally designed for an Ediswan SP61 tube.[1] A 6AU6 with somewhat lower transconductance may be employed. By using a triode, such as one-half of a 6SN7, and eliminating C_1 and R_2 slight reduction in bass boost will be experienced. The circuit can produce 4 volts rms with less than 1 per cent total harmonic distortion. Negative feedback C_2 provides output essentially independent of the actual tube gain. The mid-frequency gain is approximately unity, so that it can be inserted between a preamplifier and the main amplifier with no loss. The frequency characteristics are shown in Fig. 16.

A wide-range two-channel tone control is shown in Fig. 17.[2] Bass frequencies appear across R_2, are amplified by V_2, and fed to one grid of V_3. When R_1 is at its left-hand position, all frequencies are "flat" and fed by way of the 0.02-μf capacitor to the other 6N7 grid. Treble boost is a maximum of 5 db at 5,000 cps with R_1 arm at its extreme right position. The two halves of V_3 have common cathode coupling, but oppositely phased plates, feeding the push-pull 6V6 tubes.

V_2 is a true bass booster, controlled by R_2, independent of the rest of the amplifier. The bass response ranges from flat, with V_2 grid at ground potential, to +15-db boost at 100 cps with R_2 arm at its top. As indicated in the reference, this circuit is designed for low operating levels, where a large bass boost may be desired. Having no negative feedback, this circuit is less desirable than some. Also, as the treble potentiometer arm leaves its "flat" position there is a corresponding bass cut, which, however, may be filled in by appropriate bass boost.

Note that grid No. 3 of the input tube goes to the arm of a 200-ohm hum adjuster across the 6.3-volt heater supply.

COMPLETE AMPLIFIERS

The majority of these amplifiers are commercially available. They have been selected to show a variety of circuits, or to indicate typical circuit constants.

19. Transistor Hearing Aid. A three-transistor hearing aid called "The Listener" is compactly arranged in a plastic eyeglass frame (Fig. 18) and is powered by a single 1.3-volt mercury cell. The stages are transformer-coupled. R_1 and C_5 in Fig. 19 can be adjusted to change the peak response as much as 10 db in the 1,000- to 3,000-cps range as required. The volume control feeding the second transistor has a range of 40 db. The electrical output to the earphone is 1.0 mw. The semiadjustable ceramic printed resistor R_7 is factory-set for the proper output transistor current.
FIG. 18. Spectacle-type hearing aid.

The life per cell is about 10 days with 15 hr use per day with maximum output. The life of the cell is doubled with reduced audio output. A feature is the incorporation of the microphone in the glasses frame (Fig. 18), eliminating the clothing noise of body-worn microphones.

20. Miniature Message Repeater. This is a three-tube recorder-playback, with a maximum of 4 min of recording on a specially processed ¼-in. magnetic tape, started by an external push button. The volume control is in the grid circuit of the second half of the 12AX7 voltage amplifier. The 50B5 output tube supplies 1.2 watts to a self-contained speaker. The microphone is separate, used for the recording and then removed. A 50B5 oscillator provides 38-kc erase power during recording. A half-wave selenium rectifier and *RC* filter supply d-c voltages. Tape speed is 3¾ in. per sec; response ±3 db from 200 to 5,000 cps, which is adequate for speech reproduction in the service intended. See Fig. 21.

21. Table-model High-fidelity Phonograph. This three-tube amplifier (Fig. 22) uses push-pull 50L6 output tubes, with 5 watts maximum output, and a ceramic pickup. The second half of the 12AX7 is a phase inverter. Negative feedback is obtained by a tertiary winding on the output transformer, fed via 3,300 ohms to the first 12AX7 cathode. The feedback is greatest at low frequencies.

[1] Baxandall, P. J., Negative Feedback Tone Control, *Wireless World*, **43**, 402, October, 1952; **43**, 444, November, 1952.

[2] Hill, J. M., Wide Range Tone Control Circuit Suitable for Correction at Low Volume Levels, *Wireless World*, **52**, 422, December, 1946.

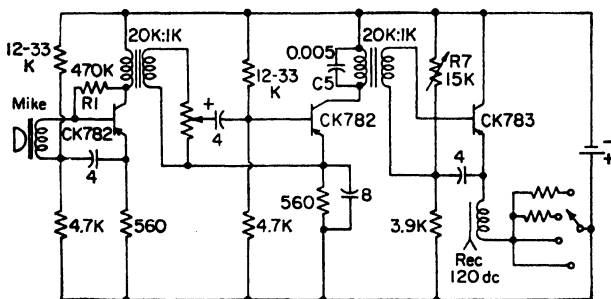
Two permanent-magnet speakers provide low-frequency reproduction, and two "kilosphere" electrostatic speakers furnish high frequencies. These speakers are polarized by 200 volts d.c. through two 6.8-megohm resistors. D-c power is supplied by a selenium doubler with a conventional *RC* filter.


FIG. 19. Transistor hearing aid of Otarion, Inc.

22. Small Public-address Amplifier. A typical small amplifier (Fig. 23) with a single 6L6 output tube has less than 5 per cent distortion at 6 watts output from 400 to 10,000 cps. At 100 cps the 6-watt output distortion is 8 per cent. The input transformer is balanced to ground for a 125- to 600-ohm microphone. Volume controls R_1 and R_7 are for microphone and crystal phono inputs, respectively. Negative feedback to the cathode of the second 6J7 includes network R_{14}, R_8, C_5, R_9, R_{10}. Tone control R_{10} decreases high frequencies as desired.
FIG. 20. Over-all response, transistor hearing aid of Otarion, Inc.

23. High-fidelity Amplifier for Home Use. A complete preamplifier power amplifier on a single chassis, with 6L6GB tubes in push-pull output, rated at 22 watts, is shown in Fig. 24. It has bass and treble controls and record-scratch and turntable-rumble filters. The inputs are for two magnetic cartridges, ceramic or crystal pickup, tuner, and tape. Response is 20 to 30,000 cps with harmonic distortion less than 0.8 per cent. Negative feedback is from the 16-ohm secondary winding of the output transformer to the cathode of the 12AX7 push-pull driver via R_{34} and C_{28} in parallel.

24. Scott Dynaural 30-watt Amplifier. This amplifier (Fig. 25) has the dynaural dynamic noise suppressor built in.[1] This is a special type of tone control to eliminate needle scratch on older records. The recorded audio signals must exceed the scratch noise to accomplish this effect. A low-frequency rumble filter is also incorporated.

Three 12AX7 heaters in series are supplied with d.c. from the output tube's bias resistor. Push-pull 1614 beam tubes provide the output with feedback from the 16-ohm output transformer secondary to one of the push-pull 12AX7 driver cathodes. Variable damping is provided, the voltage developed across the 10-ohm resistor depending on the output current drawn. Harmonic distortion is less than 0.5 per cent, IMD less than 0.25 per cent, with output usable from 4- to 24-ohm loads.

25. Williamson Amplifiers.[2] The earlier version (Fig. 26) of these amplifiers was the first to popularize excellent quality for home construction. Some of the features are negligible nonlinear distortion up to maximum rated output, linear response from 10 cps to 70 kc, negligible phase shift in the audible range, good transient response, and low output resistance. It is an all-triode power amplifier requiring 2 volts across 1 megohm for

[1] Scott, H. H., Dynamic Suppression of Phonograph Record Noise, *Electronics*, **19**, 92, December, 1946; Dynamic Noise Suppressor, *Electronics*, **20**, 96, December, 1947.

A booklet, "The Williamson Amplifier," is available for $1 from British Radio Electronics, Ltd., 1833 Jefferson Place, N.W., Washington 6, D.C.

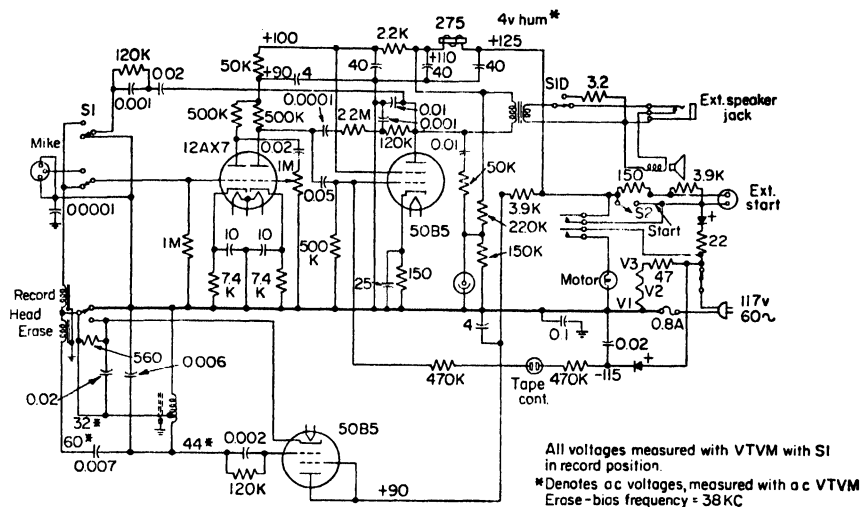
15 watts output. The input 6SN7 is direct-coupled to the phase splitter 6SN7 grid whose plate and cathode in turn feed the output stage. Ten-to-one voltage feedback, 20 db, is taken from the low-impedance loud-speaker terminals and fed to the unby-passed cathode resistor R_4 of the input triode. Feedback resistor R_{25} depends on the output transformer connection used; for 1.7 ohms output R_{25} is 1,500 ohms, for 9 ohms output it is 3,600 ohms, and for 16 ohms output it is 4,800 ohms.


FIG. 21. Circuit of Mohawk "Message Repeater," a dictation machine.
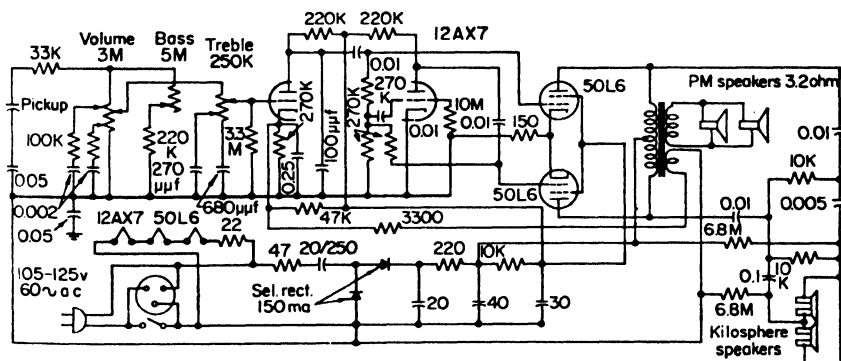

FIG. 22. Table-model home-type high-fidelity amplifier, 5 watts maximum output; two low-frequency speakers, two electrostatic high-frequency speakers (Columbia Records Model 426).

Figure 26*b* gives the frequency range with and without feedback, also the phase shift from 1 to 1,000,000 cps. This amplifier takes negative-feedback voltage around four stages. This is a severe test of design and is one of the outstanding features of the Williamson circuit.

Preliminary adjustments are made by R_{21} to bring the total plate current of the KT66s to 125 ma, and with no signal input, by connecting a 10-volt d-c meter across the plates of these tubes and by adjusting R_{17}, equal plate currents are indicated when the voltmeter reads zero.[1]

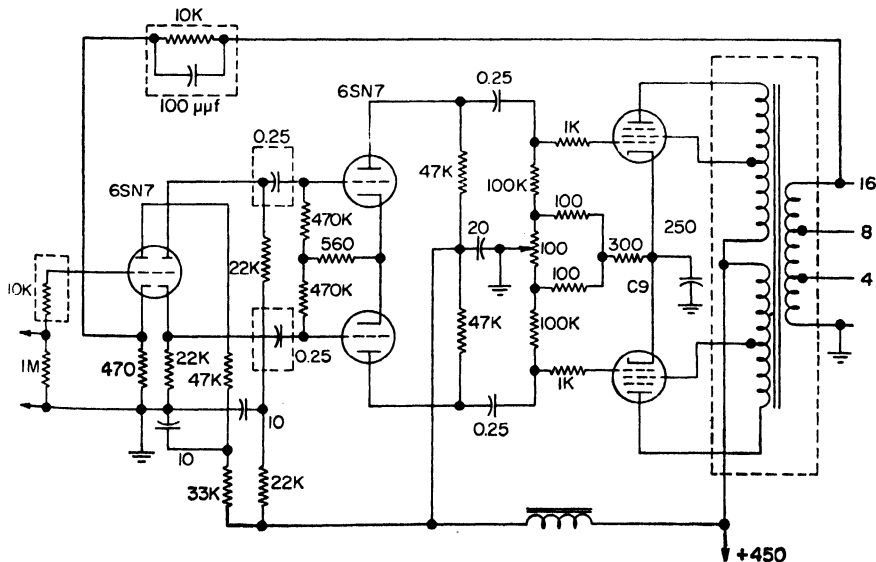
FIG. 26. Williamson high-fidelity amplifier and loop gain and phase-shift characteristics.


FIG. 27. "Ultralinear" Williamson amplifier.

Ultralinear Williamson.[1] A combination triode-pentode circuit can be used by changing the standard Williamson circuit as shown in Fig. 27. The important change is the output transformer, which may be used with 6L6, 807, 5881, and KT66 tubes. The primary impedance is 6,600 ohms plate to plate, and 1,220 ohms screen to screen, to provide the optimum combination of triode and pentode characteristics; the dotted boxes in Fig. 27 show changes from the original Williamson circuit.
FIG. 28. Intermodulation distortion, 40 and 2,000 cps mixed in 4:1 ratio.

The designers recommend C_9, a 250-μf by-pass across the output-tube cathode resistors. The output power is about 30 watts with 1-volt drive. The ultralinear circuit may be also adapted to push-pull 6550 tubes with 60 watts output.[2]

26. "Circlotron" 50-watt Power Amplifier.[3] A scheme to improve output-transformer characteristics is part of Fig. 29. Two identical d-c power supplies are provided, each supplying half the total power-stage current. The output tubes are in series for d.c., but in parallel for audio signals.[4] Because of the parallel arrangement, only one-fourth

the usual primary inductance is needed, with a consequent improvement by decreasing leakage inductance and distributed capacitance. With balanced 6550 tubes, no d.c. flows in the output transformer. The total output primary winding presents a load to each of the two output tubes. One-half the load is in the cathode and the other half in the plate circuit, the plate load of one tube being the cathode load of the other (Fig. 30). Because each tube looks at the same load as the other, the result is unity coupling between tubes. Despite the residual leakage reactance in the transformer, no switching transients occur in operation, for both tubes have the same signal current flowing.

FIG. 30. Circlotron circuit simplified.

This amplifier is rated at 50 watts ±0.5 db from 20 to 75,000 cps, less than 0.5 per cent harmonic distortion, and less than 1 per cent intermodulation distortion at rated output; hum and noise are 85 db down. Input required is 1.25 volts rms across a ¼-megohm load.

This circuit offers a variable-output damping factor from 0.1 to 10. For Klipsch speakers, for example, the damping factor is set at 10; for speakers on infinite baffles it is set at 1.0; seldom is it used below 0.5. This is accomplished by a ganged potentiometer. Current feedback to the input 12AX7 is in series with the common output and voltage feedback from the 16-ohm output to R_{4p} in the cathode circuit of the 12AX7.

FIG. 31. McIntosh 60-watt amplifier with unity coupling output transformer.

27. McIntosh 60-watt Amplifier.[1] Figure 31 is the circuit for the McIntosh MC-60 amplifier which uses push-pull 6550 tubes in a patented output circuit. This is a class B

[1] McIntosh, F. H., "Wide-band Amplifier Coupling Circuit," U.S. Patent 2477074, July 26, 1949.

circuit designed to eliminate the "notch" which occurs in the output wave form when a conventional push-pull amplifier operates both class A and class B. The driver is a push-pull cathode follower 12AX7.

The bifilar-wound transformer primary[1] gives extremely tight coupling and a minimum leakage reactance between primary windings. Each tube works into two primary sections, **one in its plate circuit and one in its cathode circuit; these sections are wound with unity coupling. This provides some feedback, but an additional output transformer winding feeds the input 12AX7 cathode by way of R_{11}, C_6, and R_7 to ground.**

Harmonic distortion is 0.3 per cent from 20 to 20,000 cps at any output level up to 60 watts. The input is high-impedance requiring 0.5 volt across 0.5 megohm.

MULTIPLE-SPEAKER SYSTEMS

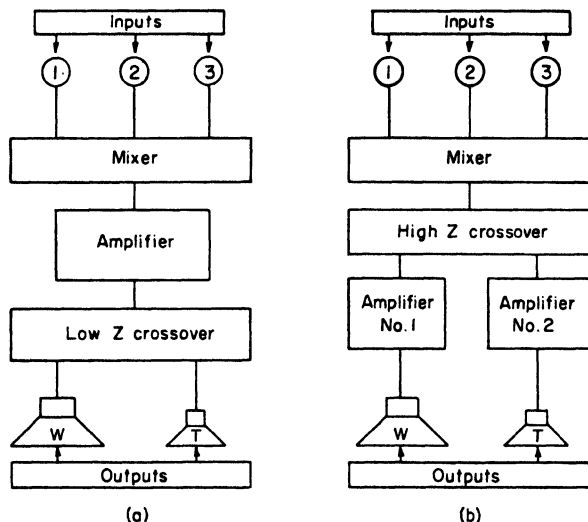
28. Crossover Networks. For reproduction of the complete audio spectrum, two or more speakers may be required, a large speaker (woofer) for the low end of the spectrum and a small speaker (tweeter) for the high frequencies. In some instances


FIG. 32. (*a*) Output crossover; (*b*) input crossover requiring two amplifiers.

a third speaker for the mid-range is employed. A crossover or "dividing" network is provided so that only the part of the spectrum for which a particular speaker is adapted is allowed to reach it.[2]

There are two general types of crossover networks: low-impedance, which are used at the output of a single amplifier (Fig. 32*a*), and high-impedance, which are used at the input of two amplifiers (Fig. 32*b*).

It is the purpose of the crossover network to divide up the ranges of frequencies, and for the low-impedance type to provide a reasonably constant output load Z_0 on the amplifier for all frequencies. Paper capacitors and air-core coils are used for the output types.

29. Two-way Output Networks, 6 Db per Octave. A series circuit is shown in Fig. 33*a* and a parallel circuit in Fig. 33*b*. The values for L and C are found from Fig. 34. Note that the bottom horizontal scale is in octaves from 125 to 4,000 cps. Following straight up from the desired frequency, there is a triple intersection: straight left is the reactance X,

[1] Corderman, Sidney A., and F. H. McIntosh, A New 30-watt Power Amplifier, *J. Audio Eng. Soc.*, **1**, 292, October, 1953.

[2] Hitchcock, R. C., A Survey of Crossover Networks, *Audio*, **40**, 28, November, 1956.

slant up left along dashed line is the capacitance, slant up right along the dotted line is the inductance. For example, at 500 cps the reactance is 16 ohms for a 20-μf capacitor and a 5.1-mh inductor. These are the values required for both circuits of Fig. 33 for a 16-ohm woofer W and a 16-ohm tweeter T, with a crossover at 500 cps, fed from an amplifier output Z_0 of 16 ohms.

30. Two-way Output Crossover Network, 12 Db per Octave. Figure 35, in which two capacitors and two inductors are used, for either the parallel or the series circuit, produces a sharper crossover. This type is safer, as it protects the high-frequency driver units from damage by low-frequency signals. Note that the subscripts are not the same for the two circuits. For the series circuit of Fig. 35*a* both inductors and capacitors have 0.71 times the reactance values shown by Fig. 34. Inductor values are linear; to get 0.71 times the reactance, the L value shown by the chart is multiplied by 0.71. Capacitor values are reciprocals; to get 0.71 times the reactance, the C value from the chart is multiplied by 1.41 for Fig. 35*a*.

FIG. 33. Two-way crossover; 6 db per octave.

For the parallel circuit of Fig. 35*b*, the desired reactance values are 1.41 times those of the chart; the inductor values are multiplied by 1.41, and the capacitor values by 0.71 as compared with the chart values. For the series circuit, 500-cps crossover, 16-ohm speakers, C_2 is 28.2 μf and L_2 is 3.6 mh. For the parallel figure under the same conditions, C_3 is 14.2 μf and L_3 is 7.2 mh.
FIG. 34. Reactance chart.

31. Three-unit Output Crossover. Figure 36 is a simple three-unit crossover. For 16-ohm speakers let f_1 be 500 cps where W starts to cut in, and f_2 be 4,000 cps where T starts to cut in. Thus L_5 for the woofer has 16 ohms at 500 cps, 5.1 mh from the chart. For the tweeter, C_5 has 16 ohms at 4,000 cps, 2.5 μf from the chart. The mid-range speaker M has a double-capacitance capacitor (half reactance) and a half-inductance coil (half reactance) in series with it. Thus C_4 has 8 ohms at 500 cps, 40 μf, and L_4 has 8 ohms at 500 cps, 2.5 mh.

A typical commercial three-way output crossover network[1] is shown in Fig. 37. As shown the amplifier has 16-ohm output, the three speakers are 16 ohms each, and the crossover frequencies are 500 and 5,000 cycles.

32. Two-way Input Network.[2] Figure 38 is a double back-to-back *RC* network designed to furnish two separate power amplifiers with high and low frequencies, respectively, each amplifier having its own loud-speaker. A cathode follower ahead of the network is recommended. Constants shown are for a crossover at 300 cycles and $R = 50{,}000$ ohms. At
FIG. 35. Two-way crossovers, 12 db per octave.
FIG. 36. Three-way crossover. For low-frequency crossover f_1, find C and L from Fig. 34. $L_5 = L$; $L_4 = L/2$; $C_4 = 2C$.
FIG. 37. Three-way crossover from Klipsch; $Z_o = W = M = T = 16$ ohms.
FIG. 38. Two-way crossover, high impedance; for 300 cps crossover, $R = 50$ kilohms; $C_H = 0.02$ μf; $C_L = 0.005$ μf.

twice the crossover frequency, $f_L = 2f_c$, the network output voltage is 12 db down (one-fourth voltage) for the low-frequency filter, and at half the crossover frequency, $f_H = f_c/2$, the voltage is 12 db down for the high-frequency filter. With subscripts L for low, H for high, and f_c for the crossover frequency:

$$f_c = f_L/2 = 2f_H \text{ cycles}$$
$$C_L = 1/(2\pi f_L R) \text{ farads} = 159{,}000/(f_L R)\ \mu\text{f}$$
$$= 4C_H$$
$$C_H = 159{,}000/(f_H R)\ \mu\text{f}$$

33. Two-way Input Crossover with No Insertion Loss. The simple circuit of Fig. 38 has no amplification since it has no tubes. Its output is one-fourth the input or is 12 db down. This may be handled by some amplifier systems but in other cases an additional stage of amplification will be needed. A versatile electronic crossover using 12AX7 tubes having no insertion loss is shown in Fig. 39. Each channel is adjustable; various responses are shown in Fig. 40. The normal operating levels are 2.0 volts input and output with a maximum of 5 volts. The low-frequency channel is flat within ±1.2 db from 10 cps to cutoff and the high-frequency channel is ±12.3 db from cutoff frequency to 20 kc.

FIG. 40. Characteristics of XO-1 crossover.

34. Multiple-speaker Power Relations. In some installations, a large number of identical permanent-magnet speakers are operated from a single amplifier output. The speakers can be in series where each has the same audio current, in parallel where each uses the same output voltage, and combinations of these two. The
FIG. 41. Ohm's law chart. (*A*) 8-ohm speaker; (*B*) 70-watt amplifier.

amplifier rated output is P_0 watts, E_0 volts, I_0 amp, and Z_0 ohms. For any individual speaker in the installation, the relations are

$$P_i = (E_i)^2/Z_i \qquad \text{and} \qquad I_i = E_i/Z_i$$

where the subscripts i indicate individual loud-speakers. Figure 41 shows these relations in chart form.[1] The dotted line on the chart shows a single 8-ohm speaker rated at 10 watts to require 9.0 volts and 1.25 amp.

[1] Hitchcock, R. C., Ohm's Law Charts, *Elec. J.*, October, 1933, p. 435.

When n speakers are used in parallel, $m = 1$; when m speakers are used in series, $n = 1$; for series-parallel, n is the number in parallel and m the number in series (Fig. 42).

FIG. 42. Multiple-speaker arrangements.

Several combinations of standard 4/8/16-ohm speakers can be made by a judicious choice of the distribution circuit. As an example, consider a 70-watt amplifier with 4/8/16/72/143-ohm outputs. If the parallel circuit is used with n speakers, each must have nZ_0 impedance. Using the 4-ohm output connection, $n = 1$ would take one 4-ohm speaker; $n = 2$, two 8-ohm speakers; $n = 4$, four 16-ohm speakers. For the 8-ohm connection, $n = 1$ would take one 8-ohm speaker and $n = 2$ two 16-ohm speakers.

The series circuit has more possibilities: $m = 1$ would be one 4-ohm speaker on the 4-ohm tap; $m = 2$, two 4-ohm speakers in series on the 8-ohm tap; $m = 4$ allows four 4-ohm speakers on 16-ohm tap, and on up to 36 series 4-ohm speakers when $m = 36$ on the 143-ohm tap. The series-parallel circuit has a great many possibilities. These can be worked out from Table 3, and by reference to Fig. 42.

Table 3. Series and Parallel Loud-speakers

No. of speakers in parallel	No. of speakers in series	P_i, watts	E_i, volts	I_i, amp	Z_i, ohms
n	1	P_0/n	E_0	I_0/n	nZ_0
1	m	P_0/m	E_0/m	I_0	Z_0/m
n	m	P_0/mn	E_0/m	I_0/n	$(n/m)Z_0$

Normally a power amplifier has enough feedback to maintain the output voltage practically independent of the load. Thus a tap on the output transformer can be regarded as being a fixed voltage line. Available on some output transformers is a tap specifically marked "70.7" volts or "100 volts." If the transformer connections are marked only in ohms, the proper tap for a fixed voltage can be found by referring to Fig. 41. For instance, a 70-watt amplifier may have 71 volts output at the 72-ohm tap (dashed line on Fig. 41), with an output rated current of 1.00 amp. Each transformer, primary has $Z_i = (E_i)^2/P_i$, where $E_i^2 = 5{,}000$ ohms for the 70.7-volt line and 10,000 ohms for the 100-volt line. Each loud-speaker takes P_i primary watts. As an example, a 70-watt amplifier with a 70.7-volt output connection may have four 10-watt speakers connected, each of whose transformer primaries has 5,000/10 = 500 ohms, plus five 6-watt speakers each of whose transformer primaries has 5,000/6 = 833 ohms. The total watts is $4 \times 10 + 5 \times 6 = 70$ watts. Of

course, fewer speakers can be used and less output employed. Each speaker transformer is matched to its individual speaker voice coil. That is, if the 6-watt speakers are 4-ohm units, each transformer is 833 ohms to 4 ohms.

Constant-line-voltage transformers are also available which have taps to match standard voice-coil impedances for specified watt ratings. The loss in the matching transformers is usually neglected, because an 80 per cent efficient transformer is only 1 db down in power at its secondary.

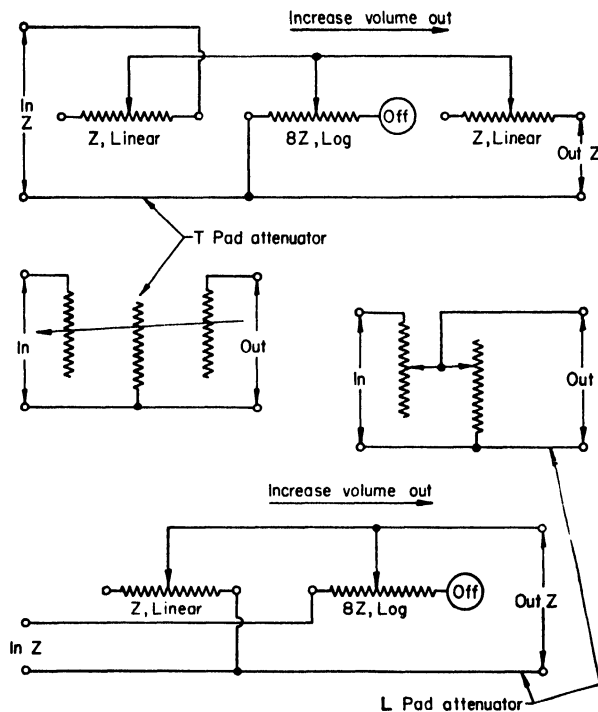
35. Phasing Multiple Speakers. When many speakers are used and where two or more may be heard at one spot, such as a ball field or a gymnasium, it is necessary


FIG. 43. Variable pads to control speaker volume.

to have each speaker correctly phased. This is readily checked with a dry cell by observing each cone motion as the voltage is applied. Each voice coil should move out when the others move out. If one moves the wrong way, its terminals should be reversed. In general, speakers are made alike and a little care in symmetrical wiring will ensure correct phasing.

36. Individual Volume Controls. In some cases it is necessary for each speaker to have its own volume control, as in hotels, hospitals, etc. An inexpensive L pad or T pad may be used. The L pad has two ganged potentiometers; the T pad has three. They are wired as indicated in Fig. 43. Control from practically zero to full volume does not materially affect either the line or the other speakers. Note that, in each pad, one of the controls has a logarithmic taper and an "off" position at maximum volume output. These pads are available for 4/8/16 ohms, and as high as 3,000 ohms. Their rating is 4 watts continuous d.c. or 15 watts peak.

37. Stereophonic Reproduction. A typical system of single-channel recording or reproducing is shown in Fig. 44*a*; a distributed source of sound is picked up by three input microphones M_1, M_2, M_3, combined to give a single composite signal, fed to an amplifier, then to the three identical speakers. A sound primarily at the left will be supplied equally to each of the three speakers.

In Fig. 44*b*, the same distributed sound source energizes the three microphones spaced as in the previous figure. But now each microphone feeds its own amplifier, there is no mixing, and each amplifier feeds its own speaker. A signal which is louder at microphone M_1 comes out louder in speaker S_1 than in the others. This is stereophonic sound—two or more pickups and output reproducers which give "three"-dimensional sound.[1]

Good results can be obtained by two independent channels. The widest possible spacing of the speakers on the long dimensions of a rectangular room is apparently better than when arranged on the narrow end of such a room.[2] Two-channel stereophonic
FIG. 44. (*a*) Single channel, three identical outputs; (*b*) three channels, stereophonic output.

phonograph records, requiring two identical pickup heads, and stereo tapes which require dual pickup heads are available. Two complete amplifiers and loud-speaker systems are needed; the realism is excellent.

COMPONENTS

38. Output Transformer. When an output transformer is used it is the most critical component in an audio amplifier. See also Sec. 49. The three most important transformer constants are the turns ratio, the primary inductance, and the leakage inductance.[3] For high audio quality it is also important to have low harmonic and intermodulation distortion. These are obtained by using a low magnetic flux, a good grade of transformer iron, and low d-c copper resistance.

The turns ratio is given by $T_{pri}/T_{sec} = \sqrt{Z_{pri}/Z_{sec}}$, where the Ts are the turns, and the Zs the impedances. For triodes the Z_{pri} required is twice to four times the plate resistance, the higher value giving lower distortion. For example for a 10,000-ohm primary and a 16-ohm secondary, the turns ratio is $\sqrt{10{,}000/16} = 25:1$. This will be suitable from plate to plate of triodes of $\frac{1}{2} \times 10{,}000$ to $\frac{1}{4} \times 10{,}000 = 5{,}000$ to 2,500 ohms.

[2] Klipsch, Paul W., Experiences in Stereophony, *Audio*, **39**, 16, July, 1953.

[3] Hitchcock, R. C., and W. O. Osbon, Design of the Output Transformer, *Electronics*, November, 1930, 381; December, 1930, p. 427.

The inductance required to obtain 10,000 ohms depends on the low-frequency response expected. Thus, if f = 20 cycles,

$$L = Z_{pri}/2\pi f = 10{,}000/(2\pi 20) = 80 \text{ henrys}$$

This is readily measured by 60-cycle power, with a voltmeter and an ammeter, where $2\pi fL = Z = E/I$; $L = E/(2\pi fI)$ with the secondary open-circuited.

The leakage inductance determines the high-frequency response.[1] To measure leakage inductance, short-circuit the secondary and measure the corresponding primary inductance at a frequency so low that the distributed capacitance is not effective, *e.g.*, 60 cycles.

The response will be 3 db down from the middle-frequency output when $\omega L_s = R_B$, where L_s is the leakage inductance and R_B is the sum of the tube plate resistance and the load resistance. Thus to be down no more than 3 db at 60,000 cps for a load of 10,000 ohms (referred to the primary) and a tube resistance of 2,500 ohms

$$L_s = 12{,}500 \div 376{,}000 \text{ or } 0.033 \text{ henry or } 33 \text{ mh}$$

When a single output tube is used, the inductance of the output transformer must be measured with the appropriate d-c flowing.

A complete design of an excellent 15-watt output transformer is given in the Williamson series.[2] The construction details refer to British core iron, wire sizes, and insulation, but the over-all performance can be matched by a first-rate transformer designer. The original Williamson output transformer has 10 primary sections interleaved with 8 identical secondary sections. Primary sections are permanently connected in series aiding, and only three leads are brought out for the 10,000-ohm plate-to-plate impedance and center tap. All secondary leads are brought out. To give the desired coupling, all secondaries are used at all times, from 1.7 ohms (all in parallel) to 109 ohms (all in series) in the original design. The essential characteristics are primary inductance 100 henrys measured at 50 cycles at 5 volts rms, primary d-c resistance 250 ohms, leakage inductance 22 mh.

Transformer connections can be determined by use of simple equipment in case the designations of the various windings have been lost. The procedure as applied to an output transformer is given below.

With an ohmmeter find out how the several windings are related to each other, *i.e.*, if they have any electrical connection, and to determine which the several windings may have been designed for. Apply a-c voltage, 60 cps, from a Variac to the winding of the highest d-c resistance (assuming that this is an output transformer). Measure the a-c voltage across each pair of leads. Calculate the turns ratio from the ratio of primary voltage to the voltages measured across the several pairs of leads. Calculate the impedance ratio (turns ratio squared) for each set of values.
Fig. 45. To determine transformer data.

With the secondaries open, measure the a-c current through the primary with known voltage applied. This gives the impedance of the primary. Assume that this value is four times the plate-to-plate impedance of the tubes to which it will be connected. Finally, using this impedance value, calculate the impedances the several secondary windings are designed for.

Example: The transformer has three windings, one with a center tap, one with numerous taps, and one with no tap. In Fig. 45 is the relation among the windings as determined by d-c resistances and in Table 4 are the various measured and calculated values. In this case it was found that, with 50 a-c volts, 60 cps, applied to the primary a current of 3.3 ma resulted, indicating a reactance of 15,200 ohms. This accounts for the value 3,800 in the table. Winding J to K is a feedback winding.

39. Output Tubes. Tables 5 and 6 are compiled from tube-data sheets. Beam-power tubes are variously called "tetrodes," "beam-power tubes," "power pentodes,"

or just "pentodes." Each has a beam-forming electrode connected internally to the cathode. In a voltage pentode this would be the suppressor.

As an approximation, the maximum audio-power output available from two identical push-pull beam pentode tubes, class AB-1, is equal to half the rated dissipation of the plates and grids of the two tubes. If a low figure of distortion is important, the output power will be less than this. Also, to an approximation, the maximum audio-output power from identical push-pull triodes, class AB-1, is about one-fourth the plate dissipation of the two tubes.

Table 6. Triode Output Tubes, Two Tubes, Class AB-1, Push-pull

† Fixed bias.

Push-pull vs. Single Tube. More than twice the output can be obtained from two push-pull tubes than for one such tube alone. Usually this figure is 2.2 for beam pentodes, because of the allowable increased bias. The converse is also true; a single class A tube can handle 0.45 times the output power of two such tubes in push-pull.

Triode Output Tubes. The class A output for triode-connected pentodes with grid No. 2 connected to the plate is about one-third that of the same tubes class AB-1 as pentodes. For classes A and AB-1 no control-grid current may be drawn; so the driving peak voltage must be less than the bias voltage. With −15 volts grid No. 1 bias, a single tube may be driven to a value just less than 15 volts. Since the rms value of a sine wave is 0.707 times its peak, this fixes the allowable rms drive voltage. Thus −15 volts peak has $0.707 \times (15) = 10.6$ volts rms. A pair of push-pull tubes, each biased at $-E$ volts, can be driven with $2E$ peak volts grid to grid, or $1.41E$ volts rms grid to grid. This applies to either pentode or triode classes A and AB-1.

40. Interstage and Input Tubes. The major criteria for a good voltage amplifier tube are voltage gain, freedom from noise (leakage, thermal, and microphonics), and minimum hum due to a-c heater. If one or more of the above are neglected, there are literally dozens of tubes which would be suitable for audio amplifiers. There are at least three tubes which have been designed specifically for audio work, meeting the above criteria. These are 5879,[1] 6BK8/Z729,[2] and 12AY7. The minimum hum for any dual heater tube is obtained with the 6.3-volt connection. When these tubes are used on d.c. the 12.6-volt connection may be used. Table 7 includes the special audio tubes and some others often used. Table 8 shows some typical operating conditions for 5879 and 12AY7.

‡ At output of 1 volt rms and grid No. 1 bias of 1 volt.
¶ This is peak (1.41 times rms) for approximately 5 % total harmonic distortion.

41. Resistors and Capacitors. Audio amplifiers use several types of resistors and capacitors. Fixed resistors are usually of the carbon-filament type provided with tightly fitted external insulating shells. The units purchased to standard ±5 per cent tolerances are used in matched push-pull circuits, for example, R_1 and R_2 in Fig. 46. In the 1-megohm range these resistors will hold their values within ±5 per cent at 40°C ambient and with a 40°C rise in temperature.

R_1 and R_2 can be checked for balance by reading d-c voltages E_1 and E_2, which, if V_1 and V_2 are matched, will read the degree of static balance. Further checking can be made if V_1 and V_2 are separate tubes, *i.e.*, not a dual-type tube, by interchanging them and again reading E_1 and E_2. If the voltages come out the same as before, I_1 and I_2 are alike and equal to E_1/R_1 and E_2/R_2.

Fig. 46. D-c checks of push-pull stages.

Precision carbon resistors with 1 per cent tolerance are also available in ½-, 1-, and 2-watt ratings. These are slightly larger than the

others for the same rating. Precision resistors usually have low noise and are desirable for preamplifier stages. The temperature coefficient of resistance of one type varies from −0.005 per cent for 10-ohm resistors to −0.02 per cent per degree centigrade rise for the ½-megohm resistors—about half that of ordinary resistors.[1] These precision resistors are available either insulated or noninsulated. A noninsulated resistor runs cooler per watt than an insulated resistor.

Vulcanized resistors are also made which have very low noise, a typical specification "corresponding to a change of resistance of one part in a million over the audio range."[2] These resistors have a temperature coefficient varying from +0.2 per cent for 5,000-ohm units to −0.4 per cent per degree centigrade for 10-megohm resistors, in the temperature range 27 to 77°C.
Fig. 47. Potentiometer tapers.

Fixed resistors with low ohmage values are wire-wound (WW) and available in 4, 5, 7, 10 watts and higher. A typical temperature rise is 290°C for full rated load on a 10-watt wire-wound resistor.[1] In Fig. 46 R_9 would probably be wire-wound to handle the output-tube plate currents.

Temperature-sensitive resistors are desirable in some power-supply systems; see Sec. 42 and Table 9.

Potentiometers are used for volume and tone controls and hum adjustment. Wire-wound controls have linear curves but carbon or composition types may be any one of the characteristics shown in Fig. 47. In logarithmic curve C tapers, 10 per cent of the resistance is contained in a 50 per cent rotation of the arm. This is "audio" taper.

For audio amplifiers mica capacitors are recommended where high power or high frequencies are encountered as in feedback circuits; see C in Fig. 76.

Coupling capacitors such as C_4 and C_5 of Fig. 46 are paper types. For the output stage to receive a balanced signal at all frequencies, the C_4, R_6 circuit must match the C_5, R_8 circuit. Thus both capacitors and resistors must be matched. The capacitors must also have high insulation resistance. To test this, with tubes V_3 and V_4 removed, the d-c currents I_4 and I_5 should be zero. When V_3 and V_4 are inserted, grid currents I_7 and I_8 should be very low, at most a few microamperes for class AB-1. If C_4, for example, allows an appreciable current to flow, the bias of V_3 will be wrong, as current will flow through R_1 and C_4. Paper capacitors are also used for by-pass. Here, too, the leakage must be very low, to ensure proper voltage applied to grid No. 2 of V_1.

Electrolytic capacitors may have an insulated outer shell of cardboard, or an outer conducting shell of aluminum. The shell is the negative terminal. The polarity must be observed.

In Fig. 46 an electrolytic C_9 by-passes R_9, the output-tube common-cathode resistor. Leakage current of a fraction of a milliampere per microfarad will be common but I_{10} must be small compared with I_9 for the capacitor to be effective. The reactance of C_9 at the lowest frequency desired must be smaller than the resistance of R_9 in ohms.

POWER SUPPLIES

Power-supply circuits furnish plate, grid, and filament or heater power to the amplifier tubes. The d-c supply for plates and grids includes a rectifier and filter.

[1] International Resistance Co.
[2] S. S. White Industrial Div.

The heater supply is usually a.c. from a 6.3-volt transformer secondary, though series strings of tubes with the same a-c heater current are becoming more popular, now that controlled warm-up-time characteristics are available. For some front-end circuits of high-gain amplifiers, d.c. is supplied to the heaters (see Fig. 25).

42. Power-supply Considerations. Rectifiers are chosen for one or more of the following characteristics: average and peak current, reverse voltage peak, ambient temperature and allowable rise, warm-up time, heater-to-cathode voltage, regulation (no-load to full-load voltage drop), back current (leakage or reverse current).

The power-output tubes take the largest amounts of d.c. and usually are indirectly heated (cathodes electrically but not thermally separated from the heaters). Until these heater-type tubes warm up, the initial d-c voltages are considerably higher than the final or working voltages. Two schemes are available for minimizing this. First, an indirectly heated cathode tube such as 5V4G or 6X5 may be used; or second, a series resistor having a negative temperature coefficient of resistance may be used. The latter have a high resistance when cold and when small currents are drawn, and low resistance when hot and when the normal load current is drawn.
Fig. 48. Half-wave rectifier. R is a current-limiting resistor.
Fig. 49. Full-wave doubler. Point X is used when balanced-to-ground voltages are required.

In Fig. 24, note that a 33-ohm resistor is in series with the positive lead of the rectifier tube. This minimizes the surge of starting current in charging the first filter capacitor. Where the current required is not too high or where the regulation is not important, resistors like the series elements in the filter work satisfactorily as in this circuit. Chokes have less d-c voltage drop and produce a better regulation characteristic than resistors as compensation for their greater weight, volume, and cost. For heavy-duty power amplifiers it is essential that steady d-c voltages be supplied to the screens of the power tubes. Voltage-regulator tubes of the VR(OC) type are employed for this purpose.

43. Notes on Power Supplies. Figure 48 is a simple half-wave rectifier in which D_1 may be a single diode or half of a double-diode tube or a metal rectifier consisting of several identical units in series if selenium or a single unit if silicon. Note that one d-c terminal is electrically connected to one a-c terminal. This is often advantageous if the common terminal can be grounded but is dangerous if the a-c plug is reversed. In Fig. 49 neither d-c terminal is directly connected to either a-c terminal.

Resistor R prevents excessive surge currents from flowing into the capacitors when first connecting the rectifier to the a-c line. Point X may be used when a balanced-to-ground power supply is needed. This circuit would then amount to two half-wave rectifiers like Fig. 48 connected back to back.

In Fig. 50 one side of the output is connected to one side of the a-c line.[1] In Fig. 51 this is avoided and in addition the capacitor negative terminals can be common.[2]
FIG. 50. Half-wave doubler; a-c line common to d-c negative.
FIG. 51. Half-wave doubler, capacitor negatives common.

Regulation of Half-wave, Full-wave, and Doubler Circuits. Figure 52 shows the comparative regulation for the circuits just mentioned.[3] The input for each circuit is 117 volts 60 cycles. Rectifiers are four 25Z6 tubes, a total of eight diodes. The total capacitance is 48 μf (paper type) $\pm 5\%$. For doubler circuits each "diode" is four parallel diodes, and each capacitor 24 μf.

For all loads the full-wave doubler supplies the greatest voltage. The half-wave doubler falls off rapidly with load, and the half-wave rectifier shows the least change of voltage with increasing load current, *i.e.*, the best regulation. At heavy output current, the voltage on one capacitor of the doubler reverses, and an electrolytic is not recommended.
FIG. 52. Rectifier regulation characteristics.

SPECIAL CIRCUITS

44. Phase Inverters. Most audio inputs are single-ended, having two terminals, one at ground potential and one varying according to the audio signal impressed. This "unbalanced-to-ground" system is often carried through the amplifier to the output stage. Here push-pull operation is usually desired. This requires a three-terminal connection, the center being the reference ground and the other two being balanced to ground. The nonground terminals alternate in voltage above and below ground. The various methods for changing unbalanced to balanced circuits are called phase splitters, phase inverters, concertina, paraphase, etc.[4] Criteria in selecting the most suitable phase inverter are linearity, voltage gain, and maximum voltage available.

Split-load Inverter. In Fig. 53 a triode drives a phase-splitting triode. The plate-load resistor is split, one-half being in the plate circuit and the other half being in the cathode circuit R_3 and R_4. Equal resistors R_5 and R_7 are the grid returns for the following stage. The gain of V_2 in Fig. 53 is less than unity; the peak-to-peak voltage from points 1 and 2 is

[4] Langford-Smith, F., "Radio Designer's Handbook," 4th ed., p. 522, RCA, 1953.

less than that supplied by the driver. Linearity is best for small voltage swings and for matched tubes and resistors R_3 and R_4.

A simplified phase splitter is employed in the Williamson circuit (Fig. 26), where the triode input-tube plate is connected directly to the grid of the phase splitter 6SN7. The voltage drops are adjusted by R_3 and R_4 so that the grid bias is normal for the 6SN7.
FIG. 53. Split-load (R_3R_4) single-tube phase inverter. No gain from V_2.
FIG. 54. Tapped-grid resistor (R_5R_6), two-tube phase inverter.

Push-pull outputs are developed at the plate and cathode of this tube because of the matched load resistors R_5 and R_7. To use low-voltage swings, the push-pull 6SN7 tubes provide additional amplification.

Two-tube Phase Splitter. In Fig. 54, V_2 and V_3 are identical and may be a dual triode with a single cathode. The grid resistor for the following stage is R_5 and R_6 in series, with the relations

$$R_5 + R_6 = R_7 \quad \text{and} \quad R_5/R_6 = VG$$

where VG is the voltage gain of V_2 for the voltages and resistors used. Control grid of

V_3 is fed from the junction of R_5 and R_6 with phase-reversed voltage, so that, in turn, the plate of V_3 can feed terminal 2 with reversed voltage (as referred to terminal 1) with respect to ground. V_2 and V_3 each give normal triode gain. R_3 and R_4 should be matched for balanced operation. Omission of by-pass capacitor across the bias resistor R_2 gives better balance in this circuit.

Slightly better high-frequency response can be obtained by separating R_3 into two sections with the same ratio as the voltage gain of the tube, feeding the grid of V_3 via a
Fig. 55. High-gain phase splitter. R_9 and R_{10} in parallel for audio frequencies match R_{11}.
Fig. 56. Cross-coupled phase inverter. R_1 is balance adjuster.

blocking capacitor from the junction, and connecting a resistor to ground from the grid of V_3 for bias.[1]

High-gain Phase Splitter.[2] In Fig. 55 the actual phase splitter V_2 is a triode with less than unity gain, but the pentode driver has six times the usual voltage gain for such a circuit, 1,200 being cited in the reference. Tubes in the original circuit were EF36 pentode driver and triode-connected EF36. Practically the same results may be obtained with type 5879, 6SJ7, or 6J7. The plate resistor R_{11} is matched by R_9 and R_{10}, which are effec-

[1] Cocking, W. T., Push-pull Input Circuits, *Wireless World*, **54**, 85, March, 1948.

[2] Jeffrey, E., Push-pull Phase-splitter, High-gain Circuit, *Wireless World*, **53**, 274, August, 1947; reprinted in "High Quality Amplifiers," Iliffe and Sons, Ltd., London.

tively in parallel for signal frequencies. The maximum output voltage for V_2 is limited because the voltage developed is split into two parts, as in Fig. 53.

Cross-coupled Phase Splitter.[1] In Fig. 56 V_1 and V_2 are low-mu cathode followers with less than unity gain, and V_3 and V_4 are high-mu triodes. Resistor values are shown for 6SN7 and 6SL7 tubes. The control-grid voltage of V_4 is the difference between the output voltage of V_1 and V_2, and the grid voltage of V_3 is equal and opposite to that of V_4. When a small positive voltage is applied between inputs 1 and 2 to the grid of V_1, the slightly reduced signal appears across R_{k1} and no signal appears across R_{k2}. But the grid of V_3 goes slightly positive and the cathode of V_4 goes slightly positive. The latter is equivalent to the grid of V_4 going slightly negative. Thus a balanced signal is developed at the grids of V_3 and V_4, and appears at the output terminals 4 and 5.

Potentiometer R_1 serves to balance the circuit. This is best done with an oscilloscope and an audio signal.

This circuit may be used so as to mix two independent inputs, each input balanced to ground, providing push-pull outputs. If tube and circuit are matched, the same signal applied to points 1 and 3 will cancel, giving no output. One use of this is a high-impedance phonograph connected at 1 and 3; any hum pickup along the line will not produce hum in the output.

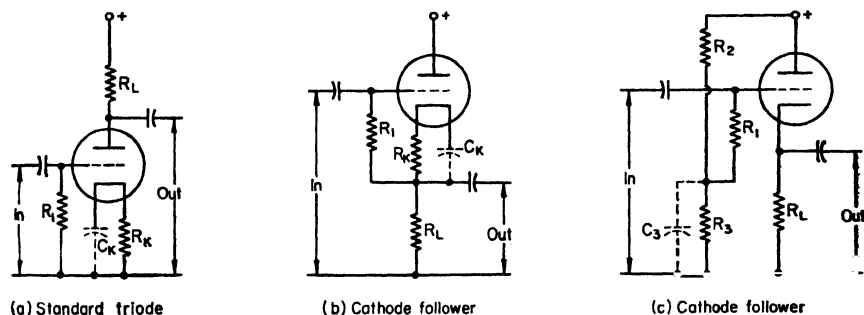
If only one input is desired, the other may be used for a tone control,[2] or if one input is connected from 1 to 2, terminals 2 to 3 may be used for negative feedback by changing R_2 to a low value, of the order of 100 ohms, and feeding point 3 from the output transformer secondary.


FIG. 57. Standard triode (*a*) compared with cathode-follower stages. In (*c*) bias is obtained from potential divider across plate-voltage supply, thus overcoming some or all of the high negative voltage produced across R_L.

45. Cathode Follower.[3] In a typical cathode-follower stage the voltage gain is 0.8 to 0.95. Its advantages for audio circuits are: (1) its output impedance is low and is largely independent of the circuit which it feeds, (2) it has a very low distortion because of its 100 per cent negative feedback, and (3) it has extremely wide frequency range. Figure 57*a* is a standard triode amplifier circuit with R_L load resistor in series with the plate of the tube. An increase of grid volts decreases the voltage at the plate, and the voltage gain is

$$(E_{\text{out}})/(E_{\text{in}}) = \mu R_L/(r_p + R_L)$$

where μ is the voltage amplification of the tube, R_L the load resistor, and r_p the plate resistance.

Figure 57*b* shows R_L transferred to the cathode circuit. In this circuit the whole tube is shifted toward the positive terminal by the voltage drop across R_L. The

[1] Langford-Smith, F., "Radio Designer's Handbook," 4th ed., Fig. 15.43A, p. 663, RCA, 1953.
[2] VonScoyoc, J. N., A Cross-coupled Input and Phase Inverter Circuit, *Radio and Television News*, **40**, 6, November, 1948.
[3] Albert, A. L., "Fundamental Electronics and Vacuum Tubes," rev. ed., p. 331, Macmillan, 1947. Schultz, T. J., Triode Cathode-followers, *IRE Trans. (Audio)*, **AU-4**, 42, March-April, 1956. Crowhurst, Norman H., Getting the Cathode Follower Straight, *Radio-Electronics*, **25**, 50, December, 1954.

grid bias is supplied by R_k as before. An increase of grid voltage by an input signal brings up the cathode voltage (follower action). The output voltage is less than that of the input because of the 100 per cent feedback. The voltage gain of the cathode follower of Fig. 57*b* is

$$\frac{E_{out}}{E_{in}} = \frac{\mu R_L}{r_p + R_L(1 + \mu)}$$

This is approximately $\mu/(1 + \mu)$ when $\mu > 20$.

The equivalent output impedance is

$$Z_0 = \frac{R_L r_p/(\mu + 1)}{R_L + r_p/(\mu + 1)}$$

when R_L is greater than r_p and μ is greater than 20, approximately

$$Z_0 = r_p/(\mu + 1)$$

In Fig. 57*c*, the junction of R_2R_3 supplies grid voltage above ground and serves to maintain the grid bias point more or less fixed even though the grid takes current on high input voltages. C_3 is optional.

The Miller effect of amplified input capacitance gives a shunting effect for the standard triode circuit of Fig. 57*c*, thus limiting the high-frequency response. The cathode follower has a reduced input capacitance, an inverse Miller effect. This is effective mainly at frequencies of 50,000 cycles and higher, above the usual audio range. A tone-control circuit is a good place to use a cathode follower (see Fig. 14). The cross-coupled phase inverter in Fig. 56 uses two cathode followers; the preamplifier of Fig. 7 uses two cathode followers. Another place for a cathode follower is at the output of a preamplifier, as in Fig. 7.

46. Volume Expander. A volume expander increases the usable dynamic range by providing higher amplification to a large input signal than to a small input signal. This is of interest mainly where soft music is to be played very softly with a minimum of background noise, and loud passages are to be played very loudly. The ideal expander should react quickly to an increase in input-signal level but decrease its amplification more slowly when the signal level goes down. The circuit[1] of Fig. 58 is a single-ended "surgeless volume expander."

This is accomplished by using two cross-connected 6SJ7 tubes, the No. 2 grid and plate of V_1 being connected, respectively, to the plate and No. 2 grid of V_2. Three metal rectifiers are shown: Se_1 and Se_2 are the doubler plate supply; Se_3 provides −48 volts bias.

With no input voltage, the d-c bias across R_2 is applied to the suppressors of V_1 and V_2. With bias set for zero volts the amplification is a maximum and is a minimum at −48 volts. When an audio signal appears across R_1 it is amplified by V_3, rectified and doubled by V_{4a} and V_{4b}, putting d.c. across 470 K filtered by C_1. These are in series with the suppressors of V_1 and V_2, bringing them above the setting of bias as indicated by R_2, increasing the amplification (unless R_2 was already set for maximum amplification). V_{4c} prevents the suppressors from going positive.

When a change in bias is applied to the suppressors of V_1 and V_2, the dynamic change in plate current in V_1 is balanced by an opposite change in screen current in the V_2. Screen-current change in V_1, similarly, is canceled by a plate-current change in V_2. As a consequence, the variation in effective transconductance of V_1 is obtained without current surges in the output.

Attack time is 0.02 sec for 75 per cent of final gain, and decay time is 0.5 to 1.2 sec for fast or slow, using switch *S*. The maximum useful range is 15 db. Maximum signal input is 0.3 volt, maximum output signal 4 volts.

47. Compressor. For the circuit of Fig. 59[2] with a strong input signal the amplification is a minimum; with a weak input signal the amplification is a maximum; the

[1] Butz, A. N., Jr., Surgeless Volume Expander, *Electronics*, September, 1946, p. 140.
[2] Kenney, T. C., KDKA private communication.

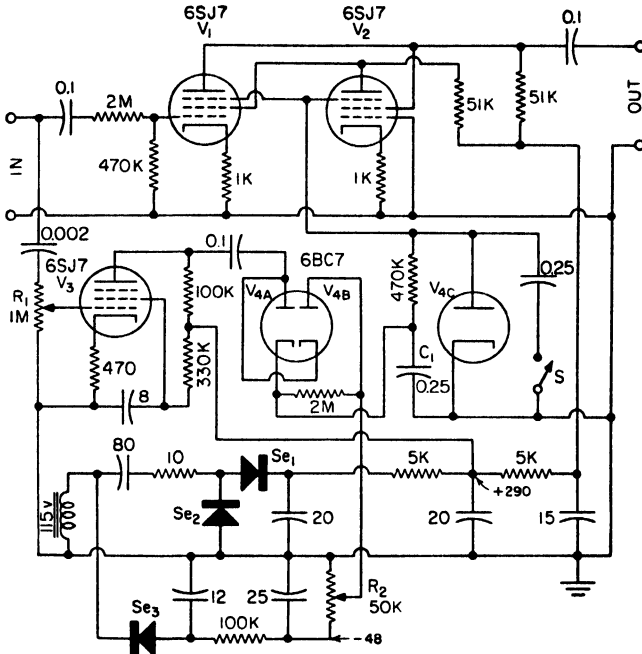
output signal is compressed, covering a smaller dynamic range than the input. This keeps the modulation at a desirable maximum, even though the input level drops drastically. This is not to be used where a large dynamic range is desired. For this case switch S is set on 2, for straight-through amplification. Push-pull operation eliminates the surge which is characteristic of most single-ended expanders, though not for Fig. 58.


FIG. 58. Surgeless volume expander. Note cross connection of No. 2 grid and plate of the two 6SJ7 tubes, preventing surges in output. V_3 is amplifier with output doubled by two-thirds of V_4 and filtered to provide d.c. across C_1 and, depending on bias from R_2, applied to grid No. 3 of both 6SJ7 tubes. Switch S affects decay time only. Maximum useful range is 15 db. Input 0.3 volt, maximum output 4 volts.

The time delay with components shown is 7 sec; with smaller values of capacitance, the delay will be shorter. This circuit will take care of drops up to 30 db in studio level, with essentially constant output.

When S is in position 1, for low-level input signals, the No. 3 grids of V_1 and V_2 are close to ground, since no voltage is supplied from V_4, T_3, and T_2. Thus maximum amplification is obtained. For high-level input signals, T_2 supplies T_3 with energy which is rectified by V_4 so that the No. 3 grids of V_2 and V_1 are carried negative, by way of the time-delay network. With negative voltage on each No. 3 grid, the 6L7 tubes have minimum amplification. When S is in position 2, each grid No. 3 of each 6L7 is grounded, and the time delay, 6H6, and T_3 are not effective.

The harmonic distortion varies from 1.5 per cent at 50 cycles to 0.4 per cent at 1,000 cycles and 1.7 per cent at 7,500 cycles.

48. Electric Mixing.[1] It is often desirable to control audio volume at some distance away from the amplifier. With "electric mixing" (Fig. 60) there are no variable controls in the signal circuits.

[1] RCA MI-4117 input mixer; MI-4737 compander; MI-4118 master mixer.

From one to four independent inputs may be used, one of which is shown in the figure as Mixer No. 1. Remote volume control P_R is connected to the amplifier circuit by three wires, one of which is ground. Either the internal volume control P_1 or the remote control P_R can vary the d-c bias on No. 1 and No. 3 grids of V_1, a 1612 (a selected 6L7). Thus the controls carry d.c. only and may be run several hundred feet. Three more identical input mixers may be connected at point E.

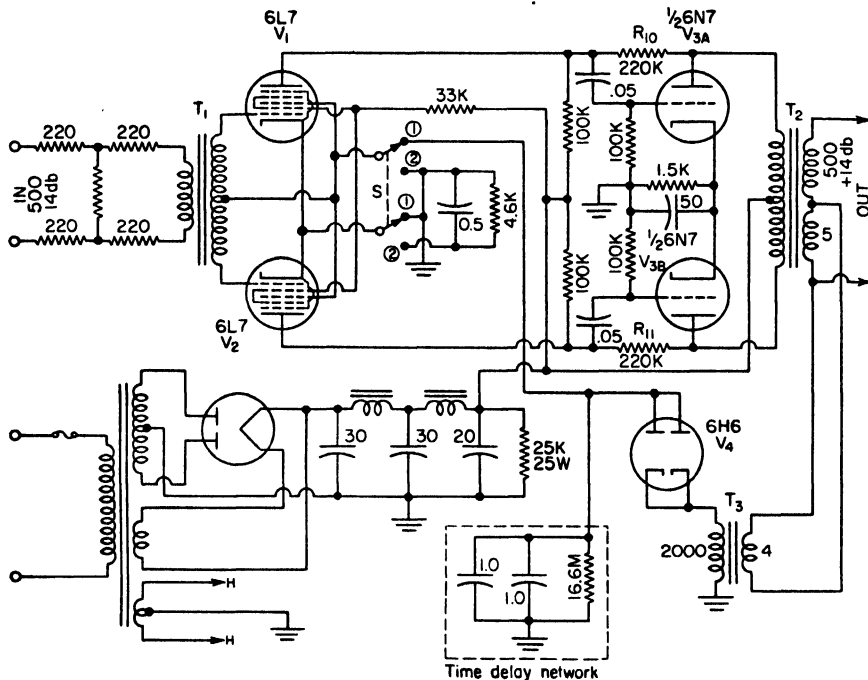
Between E and F are two capacitors, with a "music" and "speech" selector switch. At F is a dotted connection to an optional compander which may either compress the


FIG. 59. Maximum modulation amplifier (compressor). With switch S on position 1 changes in studio level will not essentially change the output. Time delay with constants shown in dotted box, 7 sec.

dynamic range or expand it. Expansion is often used with record reproduction to make a larger dynamic range than can be cut into the record. Compression is desirable for speech systems, as it minimizes the varying input, when the talker moves forward and away from the microphone.

Input F is amplified by V_3 doubled by V_4, putting d.c. across the compander volume control; the louder the signal, the more the voltage. When the compander is used the jumper across G and H is removed and the master mixer switch S_2 set in R_2 position.

The master mixer is the final volume control for the input mixers and the compander used. With the jumper in place across G and H, and S_1 at internal position (*i.e.*, not on remote R_2) the compander is not in use and the master is controlled at the amplifier by P_2.

Two-tube Mixer.[1] Five inputs are usable, four at a time, in Fig. 61. There are three independent volume controls: R_1 for magnetic phonograph pickup or high-impedance microphone No. 1 as selected by S_1; R_2 for high-impedance microphone No. 2; R_3 for crystal pickup. The fifth input is a radio which has its own volume control. At maximum gain,

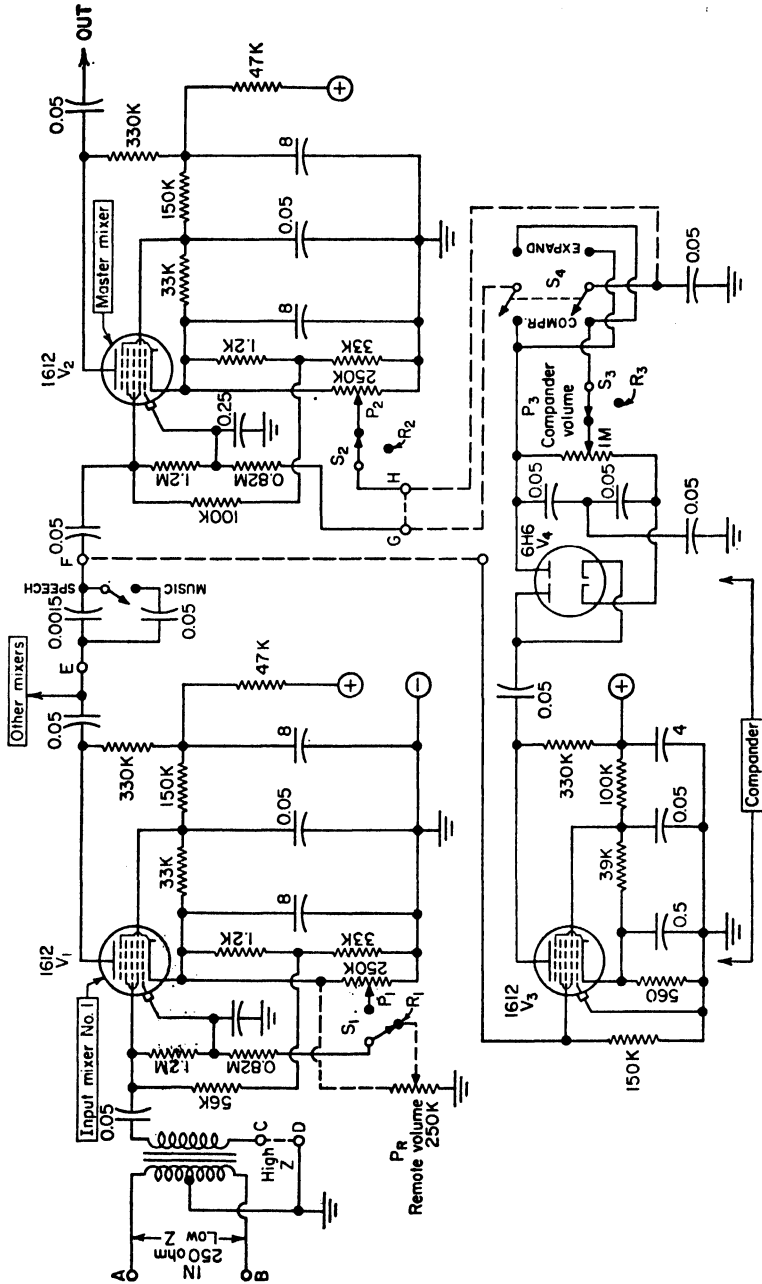
[1] Hitchcock, R. C., Preamplifier-mixer, *Popular Mechanics*, **106**, 141, August, 1946.


FIG. 60. RCA "electric mixing," shown with one of four possible inputs. With S_1 set on R_1, volume is controlled at a distant point, with d.c., no signal currents being involved. Compander amplifies and doubles the audio signal. S_3 can be set to expand or compress, as desired.
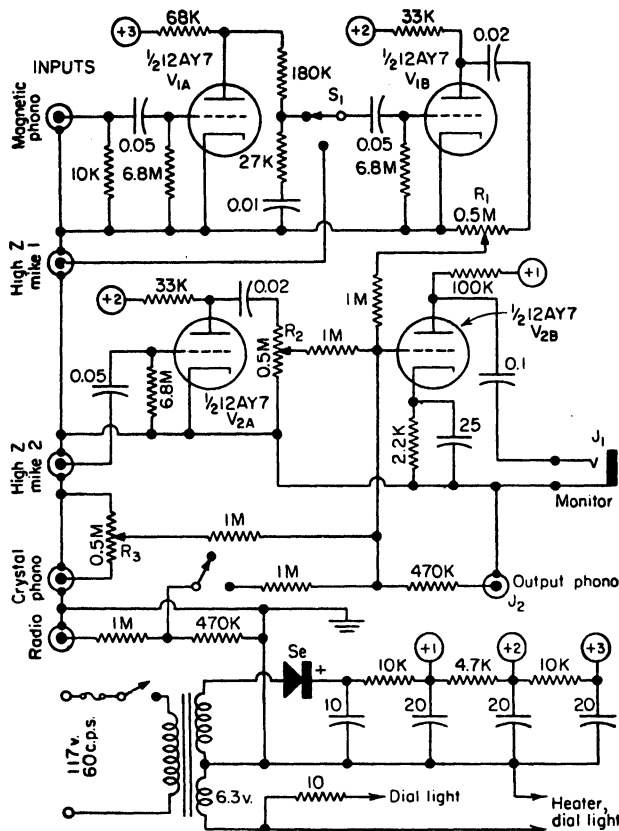

FIG. 61. Mixer for five inputs.

the inputs required to supply 0.05 volt at a 0.5-megohm load at J_2 or 2.0 volts across 0.5 megohm at J_1 are:

	Volts
Magnetic phonograph pickup	0.003
Microphone No. 1	0.01
Microphone No. 2	0.01
Crystal phonograph pickup	0.5
Radio	1.0

These are relative; thus with 0.01 volt instead of 0.05 volt output, each input would be one-fifth the values given.
FIG. 62. Monitor voltmeter. Full scale = 0.4 volt. Approximately 10,000-ohms per volt.

V_{2b} is the monitor amplifier which feeds J_1 where a 0.4-volt a-c rectifier meter (10,000 ohms per volt); Fig. 62 is the output level meter. Jack J_1 may also be used with monitor headphones without affecting the gain of the circuits feeding jack J_2. J_2 supplies the combined input signals to the microphone input of a recorder or amplifier. The regulation at J_1 is low; the voltage output with 0.5-megohm load is 2.0 volts maximum but with the voltmeter load it is 0.4 volt.

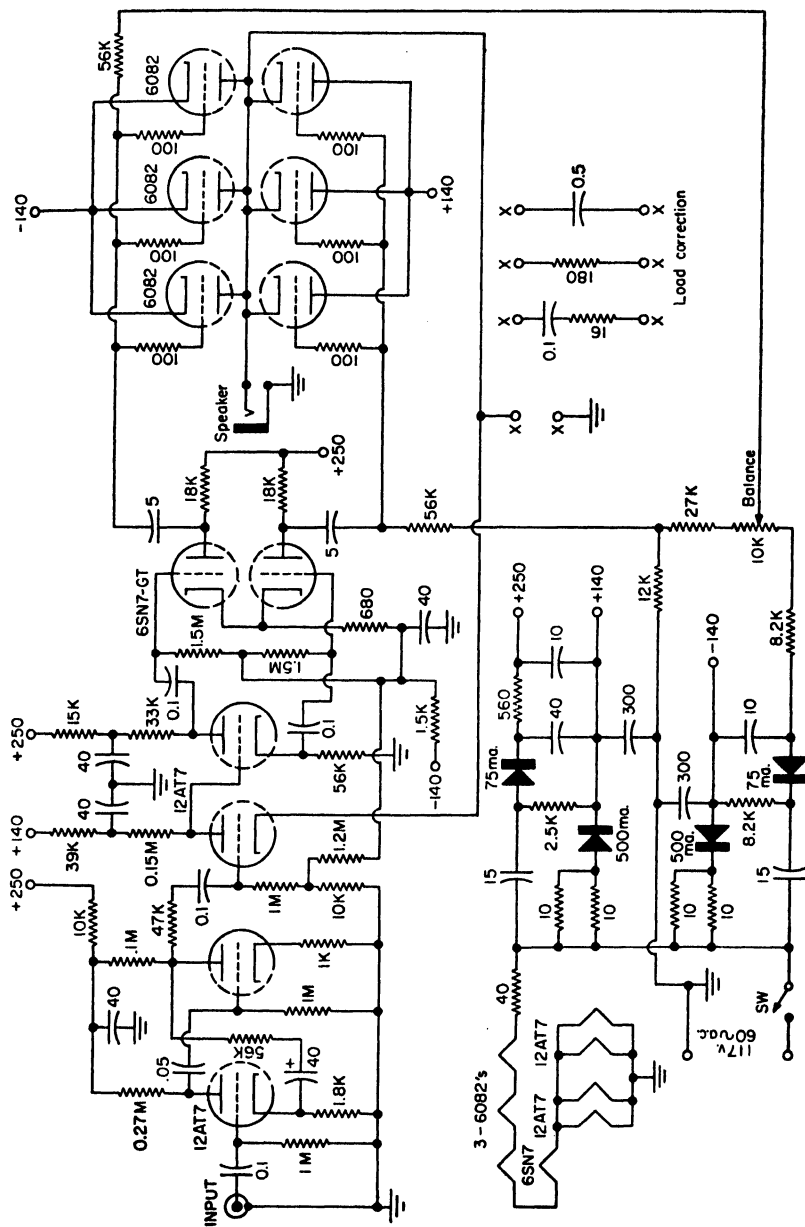
Originally designed as an input mixer for tape recorder using J_2 as output and a-c monitor


FIG. 63. Transformerless amplifier.

voltmeter at J_1, it can also be used as a preamplifier for a low-gain power amplifier, such as a crystal phonograph amplifier, which requires 0.5 to 2.0 volts input. In this case J_1 output is used.

The self-contained power supply is a 50-ma half-wave selenium rectifier and *RC* filter.

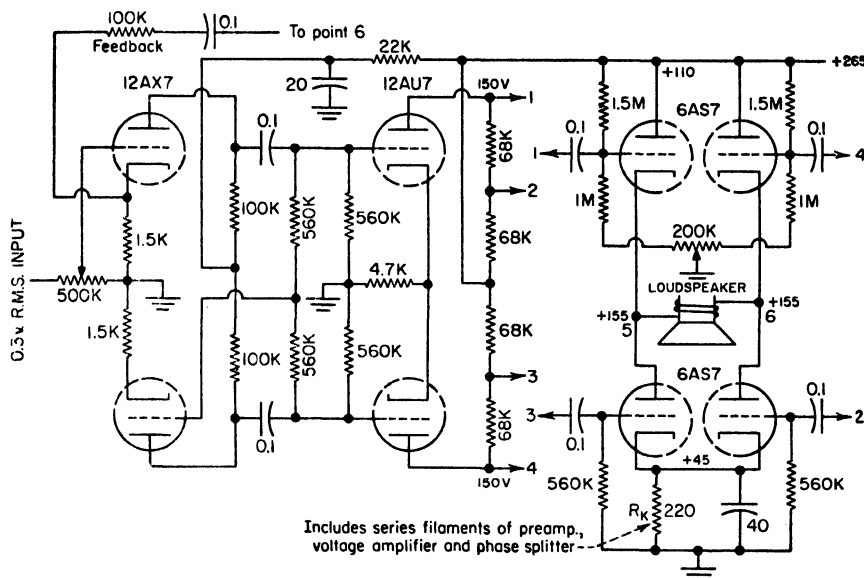
49. Circuits without Output Transformers.[1] The most critical component in an audio amplifier is the output transformer, and various circuits have been suggested to eliminate it. The major obstacle is the high impedance of the output tubes as compared with the low impedance of the loud-speakers. In general, if the output transformer can be eliminated, both ends of the audio spectrum are improved, because of the elimination of the necessity of high primary inductance for low frequencies and low leakage reactance between windings for high frequencies. Circuits without output transformers are sometimes termed "OTL," or "output-transformer-less."


FIG. 64. Transformerless amplifier. Note bridge-type circuit to match voice-coil output: 8 watts into 400-ohm voice coil.

1. Three 6082 dual-triode power tubes comprise the output stage in Fig. 63.[2] A double-ended half-wave rectifier furnishes plate power 140 volts above and below ground. The driver is a 6SN7GT with 250-volt doubler supply. With this circuit the authors obtain 25 audio watts into a 16-ohm speaker with 0.3 per cent harmonic distortion. Negative feedback of 40 db is applied from the speaker voice coil to the cathode of the phase-splitting driver 12AT7. Three possible shunt connections *XX* are suggested to stabilize speaker coils having a high inductance. Input required is 1.0 volt.

2. By using two 6AS7G output dual triodes, a type of bridge circuit[3] drives a 400-ohm speaker with 8 watts at 7 per cent intermodulation distortion without feedback, and 0.8

per cent with feedback. The output stage has four driven points, and a special plate circuit driver 12AU7 driver is employed (Fig. 64). A similar circuit[1] uses four 6082 dual triodes, and 18 watts is obtained with a load of 200 ohms.

3. Several circuits[2] use parallel 12B4 miniature noval power triodes for the output stage, with 157 volts d.c. above and below ground for plate power (Fig. 65). With eight 12B4 tubes an output of 10 watts into a 16-ohm speaker is obtained, and with 14 such tubes, 20 watts into 16 ohms. The driver is a 6S4 split-load inverter with 400-volt separate d-c supply.

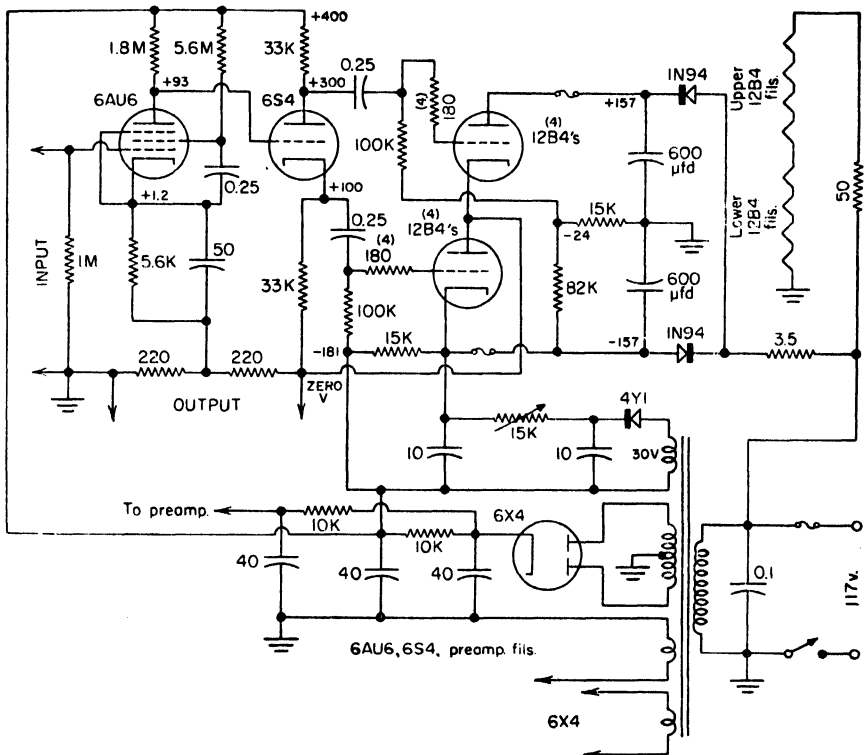
50. Synthetic Bass. By intentionally supplying only the high harmonics of a bass tone, the ear will reconstruct the tone, even though the fundamental is not


FIG. 65. Audio amplifier with no output transformer. Note output at lower left. Using eight 12B4 tubes in two groups of four, 10 watts is provided for a 16-ohm speaker.

present.[3] For table radios and other devices using small loud-speakers where no provision for baffles or boxes is possible, this scheme permits a "synthetic bass" which extends the low range an octave or two below 300 cycles although a critical musical ear will detect the excess of higher harmonics in the synthetic low.

In Fig. 66 C_1 has a relatively small value and in conjunction with R_1 will progressively reduce the passage of frequencies below 200 cps. The R_3C_2 circuit supplies strong positive feedback from V_2 to V_1 at 80 cps with decreasing feedback above this value. An incoming

wave of 4,000 cycles will be amplified in V_1 and passed on to V_2 with practically no attenuation, but practically none of it is fed back to V_1. However, V_2 amplifies this 4,000-cycle wave and passes it on to the speaker.

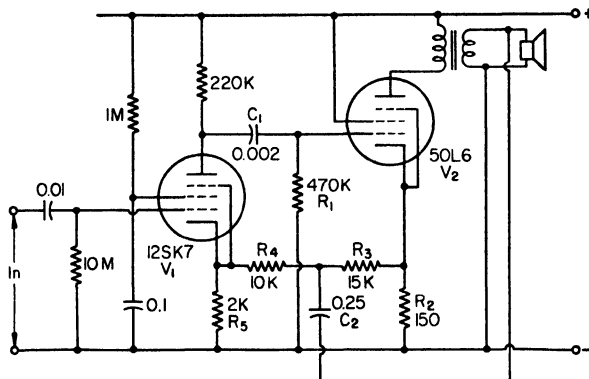
Consider now a frequency of 80 cycles. This is amplified in V_1, attenuated by C_1, R_1 and amplified by V_2. It is selectively regenerated by C_2 and R_3 and again amplified by V_1 and V_2. The curve of the output vs. input is steeper for low intensities, and this curve is accentuated when V_1 is a remote-cutoff pentode, thus encouraging odd harmonics, notably the third and fifth, which cause the ear to reconstruct the bass tone.[1]


FIG. 66. Synthetic-bass amplifier. Intentional distortion is produced by using curved characteristics of tube. Note high-frequency C_1R_1 network feeding output tube, and strong positive feedback for low frequencies via R_3R_4.

TEST EQUIPMENT

51. Voltmeter-Ammeter. A multirange d-c voltmeter is useful for checking grid bias and plate and screen voltages, both load and no-load. A cardinal principle of measurement is that the measured quantity should be changed as little as possible by the measuring device. If the current through a resistor is 1.0 ma, the voltmeter which is connected in parallel with it should take a current much smaller than 1.0 ma. As a rule, a 200-μa (or less) full-scale voltmeter is desirable, with 5,000 ohms per volt resistance or more.

Circuit diagrams often show the nominal voltages to be expected, and checking these values within 20 per cent will offer a quick analysis of the circuit. Tube testers are seldom as desirable as voltage checks of the tubes in actual service.

Figure 67 shows a two-tube amplifier with d-c voltmeters and d-c milliammeters at possible test points. Seldom will all of these be required or used.

The general plan for testing a new circuit is: find out the voltage supplied E_7. Check the power pentode V_2 first; find its grid No. 1 bias E_6. Since plate currents are usually more than ten times grid No. 2 currents, I_6 is approximately equal to I_5, and hence I_5 is very nearly the same as E_6/R_6 amp. E_{44} No. 2 grid volts should be checked; then if No. 1 grid bias is about right for the supply voltage E_7, and I_5 normal, V_2 and its circuit can be assumed satisfactory to use.

To connect milliammeters requires breaking a circuit and bringing two leads to the meter; this is not attractive because both leads have to be insulated for the voltages encountered. Insulated test clips from a voltmeter are readily attached, and usually tell enough of what is wanted to give a true operating picture of the d-c circuit. For example, $I_2 = E_2/R_2$.

52. Ohmmeter. A battery-powered ohmmeter is a useful test tool. It can be used to check circuit components: (1) resistors and potentiometers; (2) primaries

[1] Shepard, F. H., Jr., U.S. Patent 2313098, Fig. 2, Mar. 9, 1943.

and secondaries of transformers; (3) leakage of capacitors, electrolytic or paper; (4) grounds on components; and (5) short circuits.

Ohmmeter ranges are often given as "full scale" such as 1,000/10,000/100,000/1,000,000 ohms. Ohmmeter pointers normally indicate zero ohms with the pointer fully deflected toward the right, and are set at that point by an adjusting knob when the two test leads are touched together. The highest ohmages, so-called "full scale," are toward the left, with the pointer moved just slightly from the left-hand no-reading position. The precision of an ohmmeter reading is neither high nor constant, being most accurate up scale and least accurate down scale. However, it is often sufficient to determine the suitability of a component for use.
FIG. 67. Use of d-c meters to check amplifier.

To check for resistance, the component ordinarily cannot be in an energized circuit. The power supply must be cut off, and usually all but one of the terminals to the component disconnected.

Notes. Potentiometers with three leads should have at least two leads disconnected, to read ohms without including other components. Resistors with two leads can be read for ohms with only one lead disconnected. Multiple-lead resistors must have all but one lead disconnected.

The d-c resistance of transformer windings may be found with an ohmmeter, but there will be an inductive kick as the circuit to the ohmmeter is broken.

An electrolytic capacitor has appreciable resistance in either direction, but it is much lower in its reverse direction. When positive voltage from the meter is applied to the plus terminal of the electrolytic, this resistance will be the higher of the two. Some volt-ohm-milliammeters have a reversal of polarities; the positive lead for volts and milliamperes is the negative lead when used as an ohmmeter. Paper capacitors should show practically no measurable steady d.c. in either direction. There will be an initial charging kick which quickly dies to zero. A paper capacitor showing a steady deflection of 1 megohm or less is defective.

Checking resistance of various parts of the ground is often informative.

A short-circuited component reads zero on an ohmmeter. When checking resistances greater than 10,000 ohms, do not touch the ohmmeter leads. Dry-skin resistance of 50,000 to 100,000 ohms is typical, and wet hands may give a reading as low as 10,000 ohms. In placing the ohmmeter terminals, hold them by the insulated handles, on a deenergized circuit.

53. Vacuum-tube Voltmeter. These instruments usually have several ranges and are very helpful for measuring a-c and audio voltages. To measure interstage audio voltage, a series capacitor of 0.002 to 0.02 μf will prevent changing the d-c conditions. Most VTVMs read peak voltages but are calibrated in rms, assuming sine waves. This makes them read wrong for waves other than sine (see Fig. 68). Their input resistance is usually high, from 0.5 to 10 megohms, and their connection to low-energy circuits does not materially affect circuit operation.

54. Cathode-ray Oscilloscope. This is one of the most versatile of test instruments. It has high input resistance so that it does not affect the circuits across
FIG. 68. Meter indications for saw-tooth waves.

which it is connected. Linear time scanning of the beam from left to right and vertical deflection by the voltage of the circuit being studied are most often used. Time scanning from 10 to 10,000 per second includes practically all audio-amplifier work.

Connecting a cathode-ray oscilloscope across the amplifier output and watching for peaks of the amplified waves will show immediately if there is any clipping. If the clipping is in the push-pull output stage alone, the peaks will be clipped at top and bottom. If a single-ended stage is clipping, usually either the top or the bottom is flattened.

A saw-tooth oscillator (Sec. 57) plus a cathode-ray oscilloscope can give a variety of important test data (see Figs. 72 and 73): (1) flat frequency response, sharp corners, and straight lines; (2) treble boost, an extra high starting spike; (3) treble cut, rounded starting peak; (4) bass boost, a bulged center; (5) bass cut, a concave center; and (6) overload due to clipping, flat tops in saw-tooth wave.

A cathode-ray oscilloscope clearly shows gross distortion of sine waves, but considerable practice is needed to detect a small amount of distortion in a sine wave.

55. Equivalent Single-sine-wave Power. Audio amplifiers are rated at their maximum electrical output when delivering a single sine wave. Power amplifiers are rated two ways: the wattage rating for continuous sine-wave power output, and the "audio" rating. The audio rating is about twice the continuous rating. Considered here is the sine-wave rating.

To find the frequency response, sine waves of different frequencies are supplied one at a time, and the output is measured across the rated load resistor. The power input to the amplifier $P_{in} = (E_{in})^2/R_{in}$; and the power out $P_{out} = (E_{out})^2/R_{out}$, where the Rs are in ohms, the Es in volts, and the Ps in watts. The over-all response, at any specified frequency, is

$$\text{db} = 10 \log (P_{out}/P_{in})$$

Now when two sine waves are simultaneously applied, as in intermodulation testing (Sec. 56), the actual P_{out} requires a conversion factor to relate it to the equivalent single-sine-wave power. Suppose two output voltages are E_1 and E_2 and that their ratio is n so that $E_2 = nE_1$, and both are impressed on the same load resistor; the total power in the load R is

$$P_{1,2} = (n^2 + 1)E_1^2/R$$

In testing the intermodulation, $P_{1,2}$ is the actual power received by R. Note, however, that, when two waves are applied simultaneously, their peaks add together. Clipping these peaks is one cause of intermodulation distortion. In the example mentioned, the new peak corresponds to a new rms voltage $(n + 1)E_1$. The power in a resistor with this voltage would be

$$P_1 = (n + 1)^2E_1^2/R$$

So when an amplifier is tested with two waves E_1 and nE_1, giving $P_{1,2}$ power with no clipping, it really can handle P_1 single-sine-wave power, with the relation

$$P_1 = P_{1,2}(n + 1)^2/(n^2)$$

For intermodulation testing, where $n = 4$,

$$P_1 = P_{1,2}(25/17) = 1.47P_{1,2}$$

That is, the equivalent single-sine-wave power is 1.47 times the two-sine-wave power actually in the load resistor R, for a 4:1 voltage ratio or 12 db.[1]

The most accurate a-f voltmeter under all conditions is the thermocouple type because it reads true rms even for waves of different shapes. However, thermocouples are seldom used, except for checking other meters, because of their low overload capacity. Rectifier-type meters actually read rectified average, although they are calibrated to show rms sine-wave voltages. They are reasonably accurate for sine waves but the form factor of some peaked waves requires recalibration. VTVMs are peak-reading meters but also may be calibrated for sine waves. Waves other than sine will not read correctly without conversion factors. See Fig. 68 for sawtooth and the readings of these meters.

56. Measuring Intermodulation Distortion.[1] In Fig. 69 the power amplifier being tested has an output load resistor R. Meter E_{out} shows the output voltage. The input generator produces sine waves, each of controlled amplitude E_{100} and $E_{5,000}$, whose combined value is E_{in} volts. An optional but informative instrument is the oscilloscope CRO driven by an auxiliary amplifier if necessary. A quadruple bus is connected to the two four-point switches S_1 and S_2 allowing the use of the auxiliary amplifier or the VTVM direct as required.

The filter indicated on Fig. 69 is made up of a high-pass section passing 5,000 cps and a

[1] Aston, R. H., Intermodulation Measurements on Radiotron Amplifier A515, *Radiotronics*, No. 130, p. 34, March–April, 1948. Hitchcock, R. C., Intermodulation Distortion, *Audio Eng.*, **36**, 21, October, 1952. Various combinations of frequencies for IMD measurements have been suggested. For example, (1) 60:7,000; 40:12,000 cps, Standard Transformer Corp.; (2) 40:2,000; 40:7,000; 40:12,000 cps, Acro Products Co.; (3) 40:4,000 cps, Thomas Roddam, *Wireless World*, **56**, 122, 1950; (4) 60:4,000 cps, Pierce J. Aubrey, *Audio Eng.*, **35**, 22, 1951; (5) 100:7,000 cps, Cook Series 10 Record.

pi-type low-pass section passing 100 cps. Both sections are down 20 db at 1,000 cps, the two sections being isolated by a 1-K resistor across which is shun'ed a diode. A shunt resistor terminates the filter across which the distortion E_{LO} appears and is read.

An input signal E_{in} of, say, 0.4 volt E_{100} and 0.1 volt $E_{5,000}$ is applied to the amplifier, and the output E_{out} is read. E_{out} enters the filter giving E_{HI} and emerging as E_{LO}, which is read by the VTVM for one value of the input. For an ideal amplifier, E_{LO} is zero. For a real amplifier

$$\% \text{ intermodulation distortion} = 100E_{LO}/E_{HI}$$

for any given E_{out}, that is, for a given output power. The equivalent single-sine-wave power in the resistor is $1.47(E_{out}^2)/R$.

Figure 70 is a set of typical graphs[1] of E_{in} volts against E_{out} (measured), W watts (calculated), E_{HI} (measured), IMD intermodulation distortion per cent (calculated), and E_{LO} (measured) for a Williamson amplifier, using a Savage 2B36B output transformer, and an 8-ohm resistance load R.

Fig. 69. Circuit for intermodulation distortion test. Dotted circles are optional meters. Two-tone sine generator provides input. Voltage output is connected to filter. With no intermodulation distortion E_{LO} will be zero.

The distortion E_{LO} rises slowly at first, though at a faster rate than E_{HI}, showing that the intermodulation distortion is rising. Then E_{LO} rises at a still faster rate, finally tapering off.

Intermodulation-distortion figures above 5 per cent indicate a poor degree of fidelity. This amplifier, rated at 15 watts, had 0.4 per cent intermodulation distortion at that point, and with 20 watts output it had 1.3 per cent. Note that the VTVM must read rather low voltages. E_{LO} is only 0.0001 volt (0.1 mv) at the lowest reading on the figure.

57. Saw-tooth Generator. A saw-tooth generator (Fig. 71) includes all harmonics.[2] Each harmonic is smaller in amplitude than the one preceding it, the nth harmonic being $1/n$ that of the fundamental. Saw-tooth waves are more desirable for testing than square waves, since square waves contain only odd harmonics. Square waves cannot be used to show clipping of peaks, since they are already flat-topped.

The steep wave front of a saw-tooth will start an amplifier ringing if there is any tendency to do so; see Sec. 62 and Fig. 77. As corrective measures are taken, the oscilloscope will show the improvement, and when the final saw-tooth is sharp, the correction is complete (see Fig. 77).

The saw-tooth generator can also show overload due to clipping. The amplifier

[1] Hitchcock, R. C., Oscilloscope Pictures of Intermodulation Distortion, *Am. J. Phys.*, **22**, 187, April, 1954, Figs. 1 and 6 (recalculated).

[2] Hitchcock, R. C., Testing with White Sound, *Audio*, **38**, 41, October, 1954. For methods of measuring gain and loss and frequency response of audio amplifiers, see *Proc. IRE*, **44**, 668, May, 1956, IRE Standards on Audio Systems and Components.

is driven with an increasing saw-tooth voltage while the oscilloscope displays the output waves. When the tops just begin to flatten, the maximum peak-to-peak voltage-handling ability of the amplifier has been reached. From this the equivalent single sine wave can be determined. The conversion requires a knowledge of the meter being used. Thus in Fig. 68 note that a peak-to-peak saw-tooth voltage of 20 has the same maximum and minimum as a sine wave having an rms value of 7.07 volts. At 20 volts peak-to-peak bottom scale and 7.07 volts rms top scale the rectifier meter shows 5.6 volts, the thermocouple 5.8 volts, and the VTVM 7.07 volts. If this peak-to-peak saw-tooth of 20 volts is the greatest value which the amplifier will produce without clipping, the equivalent-sine-wave power is E^2/R, where E is the equivalent-sine-wave volts; the power then is $(7.07)^2/R$, where R is the terminating resistor being used.

FIG. 70. Typical intermodulation distortion (IMD) of Williamson amplifier. Solid lines show measured quantities, E_{LO} from filter output, E_{HI} from high-pass filter, E_{out} amplifier output volts on 8-ohm load. Dotted lines are calculated: output power and distortion.

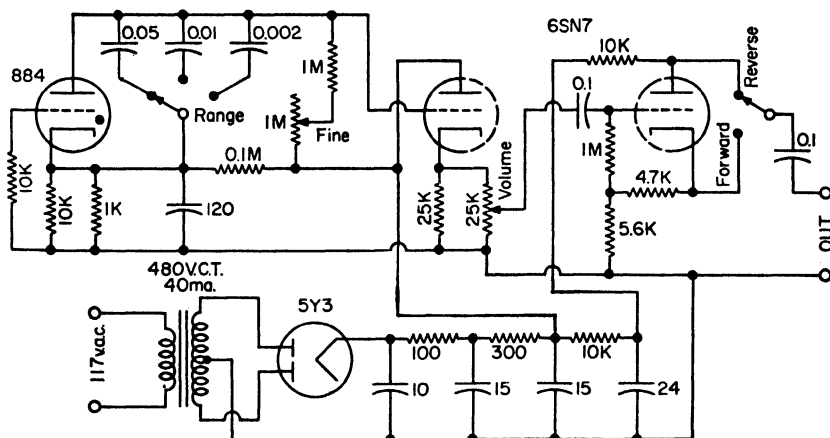
Using a resistor for a load is standard practice, and quiet. It is the first step in


FIG. 71. Saw-tooth-wave generator. Note reverse and forward switch. Nominal ranges are 100/1,000/10,000 cps. Output is 20 volts peak to peak into loads of 100,000 ohms or higher.
FIG. 72. Use of 1,000-cps saw-tooth in amplifier test, indicating overload (clipped tops and bottoms), ring (spike at top), rated load (sharp saw-tooth).

testing a new amplifier. But before the amplifier can be considered fully checked, the actual output circuit should be connected. Sometimes crossover networks provide unexpected results. The test, however, can be made at lower power, and the output voltage watched on the oscilloscope as the saw-tooth input voltage is increased. A quick way to find out the flat setting of the bass and treble controls is to have the saw-tooth come out sharp, with straight lines. A 1,000 per second saw-tooth will check bass down to 100 cps and treble up to 10,000 cps.
FIG. 73. Saw-tooth-wave interpretation. Treble response, 10 per cent; "boost" shows a spike, "flat" a sharp corner, "cut" as a rounded corner; bass, 90 per cent.

Saw-tooth Oscillator Circuit. The saw-tooth oscillator in Fig. 71 uses an 884 gas triode. The nominal ranges are 100/1,000/10,000 cps with the fine adjustment being a 1-megohm variable resistor in series with a 1-megohm grid resistor of a 6SN7 cathode follower. The final 6SN7 is a forward-reverse tube, having a split load. For single-ended amplifiers the saw-tooth should be tried both forward and reverse, as sometimes these amplifiers act differently when the saw-tooth goes negative first, instead of positive first as shown in Fig. 73. Into a load of 0.1 megohm or higher, this generator supplies up to 20 volts peak to peak.

58. Measuring Harmonic Distortion. When a single sine wave is fed to an amplifier input, the output contains the fundamental (first harmonic) plus a smaller amount of second, third, and higher harmonics. These unwanted harmonics are present to
FIG. 74. A 1,000-cycle saw-tooth shows amplifier performance when boost and cut are at 100 and 5,000 cps. (*a*) At 100 cps cut is 6 db. (*b*) At 100 cps boost is 14 db. (*c*) At 5,000 cps cut is 12 db. (*d*) At 5,000 cps boost is 8 db. (*e*) Bass boost (100) is 14 db, and treble boost (5,000) is 8 db.

some extent at all operating levels, but in general they will be greatest at the full output of the amplifier.

There are two methods of testing for harmonic distortion. Both apply a low-distortion sine wave to the input. Next the single frequency is balanced out of the output, by using a tuned bridge circuit. At this point the simpler of the two methods measures the residual output, the "total" harmonic distortion.[1] The fractional distortion in per cent is the residual divided by the full output voltage, multiplied by 100.

A more accurate method, after balancing out the fundamental at the output, is to tune in the second, third, and higher harmonics, one at a time by an additional bridge, and to measure each separately. A commercial wave analyzer for this purpose is shown schematically in Fig. 75. This is a high-gain amplifier with *RC* interstage coupling, balanced to a sharp null, a calibrated attenuator for adjusting sensitivity, and a built-in VTVM. Distortion as low as 0.1 per cent can be measured for third harmonics of fundamentals as high as 15,000 cycles and higher harmonics of lower frequencies. In addition a low-distortion sine-wave generator is needed.

Since it is usual for most audio amplifiers to
FIG. 75. Wave-form measuring circuit, used to measure harmonic distortion, made up of a high-gain amplifier, null circuit, calibrated attenuator, and VTVM. A pure sine-wave generator input is needed. (*Courtesy of General Radio Company.*)

[1] Tyler, V. J., Simple Distortion Meter, *Wireless World*, **49**, 431, September, 1953.

have a total harmonic distortion of less than 10 per cent, an approximate working formula is[1]

$$\% \text{ total distortion} = \sqrt{(k_2)^2 + (k_3)^2 + \cdots (k_n)^2}$$

where k is the per cent of the voltage at the harmonic specified by the subscript, to the output voltage.

AMPLIFIER TROUBLES

59. Hum. The possibility of 60- and 120-cycle power-line hum is always present in an audio amplifier. Perhaps it is most serious for home high-fidelity sets, where quiet surroundings enhance any extraneous sounds.[2] Commercial amplifiers usually specify the amount of hum, for example, for the amplifier of Fig. 25 as "80 db below full output," which in this case is 30 watts. Putting h as the hum decibels, P_{out} the rated power, and P_{hum} the hum power,

$$h = 10 \log (P_{out}/P_{hum})$$
$$P_{hum} = (10^{-h/10}) P_{out} = 10^{-8} \times 30 = 0.3 \times 10^{-6} \text{ watt}$$

The problem of hum can be divided into two categories: the design and construction of the amplifier, and (2) its operation and use.

1. In designing a high-quality amplifier, a schematic circuit is not enough. The actual point-to-point wiring should be shown on a scale drawing. Grid and plate circuits should be separated from each other and from a-c heater wires; high-gain input tubes should be as far as possible from the power tubes, and especially from the rectifier tube. For a "ground" a large tinned copper bus bar is advisable, connected to the metal chassis at one point. Usually the best place is at the input jack positions. No closed loops in the ground bus should be permitted. Loops may include magnetic flux from the power transformer and thus pick up hum. Instead, the bus should run from one end of the chassis to the other, with radiating jumpers to provide grounds as needed. Grounding to chassis at many points is bad practice.

Metal tubes are preferable to glass tubes for input stages, though shielded miniature tubes are satisfactory. For an input amplifier, a 6.3-volt heater supplied with 5.8 volts will give less hum. For dual voltages, 12.6 or 6.3 volts, the parallel 6.3-volt connection will produce minimum hum on a.c. With d.c. on the heater, the 12.6-volt connection is satisfactory (see Fig. 25).

2. Properly connecting the outputs and inputs to an amplifier can reduce hum. The way to start is to connect the output circuits (no inputs). Turning up the amplifier controls, bass boost, and volume should give very little or no noticeable hum. The only devices in the output circuit susceptible to hum are the air-core crossover coils. These coils should be placed several feet away from the power transformer, and not too close to the phonograph motor; both are potential sources of hum. The polarity of the power-line plug will affect the hum of an a.c.-d.c. amplifier such as Fig. 22, and to some extent any high-gain amplifier. The plug should be turned over and reinserted to find out the minimum hum.

The metal chassis of a high-gain amplifier, fed from a microphone or a magnetic pickup, will often have considerably less hum when grounded. Water-pipe grounds are best, with hot-water-heating-system pipes next best. Some tubes have more hum than others. Exchanging similar-type input tubes, to find the arrangement with least hum, is worth trying.

If more than one input is to be used, they should be connected one at a time, noting the hum for each as the volume is turned up. Leads to all inputs should be shielded cables grounded to the amplifier chassis. Input leads, even if shielded, should be kept away from the two main sources of hum, the power transformer and the phonograph motor.

60. Distortion. Gross distortion in an audio system is due to either external or internal causes. Mismatching at input or output is a frequent external cause. A crystal phonograph pickup with 0.5 volt output, if connected to a magnetic phono-

[1] Conway, T. D., Measurement of Harmonic Distortion, *Wireless World*, **60**, 110, March, 1954.

[2] Fleming, L., Controlling Hum in Audio Amplifiers, *Radio and Television News*, **44**, 55, November, 1950.

graph input, will overload the input stages of the amplifier. Since the volume control is farther along in the circuit, the voltage cannot be reduced at the input. The remedy is to use the proper input jack, or to reduce the 0.5 volt by a two-resistor voltage divider to about 0.01 volt.

Mismatching outputs has a similar effect. An 8-ohm speaker on a 200-ohm tap will not produce proper and expected volume, and the frequency range will be restricted. In driving the amplifier harder to get more output, the final stage will undoubtedly be overloaded, with bad distortion. Usually for public-address work the match from 75 to 125 per cent of the rated impedance will be close enough.

A simple trouble has a simple answer: the output terminal strip often has connections so close together that a wire may touch two adjacent terminals. This short circuit greatly reduces an amplifier output, and in trying to get sufficient volume, the amplifier is overloaded and the speaker shows it.

Internal distortion can occur because of lack of sufficient control-grid bias on the power-output tubes, which allows the plate current to increase and may cause rectifier-tube plates or the output-tube plates to get red hot.
Fig. 76. Amplifier which rings, as shown in Fig. 77, has capacitor C added across the negative-voltage feedback 600-ohm resistor.

Harmonic and intermodulation distortion are more complex and are not in the class of gross distortion.

61. Noise. Noise is any unwanted sound in an amplifier. Power-line hum is one kind. With no input connected and amplifier gain at maximum, a frying or hissing sound is usually due to a tube, resistor, or capacitor. With a microphone input, the background noise and microphone hiss usually mask any internal noises. Tubes may have leakage from heater to cathode, a resistor in a preamplifier may run too hot, or a paper capacitor may leak.

Microphonics are a special type of noise. Usually an input tube will "ring" when tapped with the finger. If the sound dies away quickly, for some installations this is not serious, but since tubes vary in this property, a better tube can probably be found and used. A high-power loud-speaker should not face or be placed too close to a high-gain amplifier input tube, nor should the speaker be too close to a low-output phonograph pickup; pickups are microphonic.

62. Oscillation and Feedback. Oscillations are unwanted frequencies in the amplifier; they may be above audible, audible, or below audible in frequency.

Supersonic Oscillations. Some amplifiers oscillate at a frequency above 50,000 cps. A high setting of treble boost may start off the oscillation, in which case a reduction of the setting will usually stop the trouble. A change in the maximum possible setting of the treble control, a series resistor, or a shunt capacitor will eliminate the oscillation. These high-frequency waves are undamped and they load the amplifier so that all audio waves are badly distorted. The remedy may also be to add a 100- or 200-$\mu\mu$f

shunt capacitor to ground at an input-stage plate. The goal is to prevent the oscillation yet permit the stable amplification of audio frequencies. An oscilloscope at the output will detect the waves, showing amplitude as well as frequency. Note in Fig. 26 that R and C are shunted across the 47-K plate load resistor of the first tube; this discourages supersonic oscillations.

Ringing. This is a case which happens oftener than might be suspected. It can be detected by watching the output voltage on an oscilloscope, as steep wave fronts are applied to the input. A typical ringing picture is Fig. 77 when the input is a 10,000-cps saw-tooth. The steep wave front starts an amplifier to ringing, if there is any tendency toward instability. Figure 76 is the feedback circuit; across the 8-ohm output transformer secondary is 600 ohms plus 10 ohms to ground, with the input-tube cathode connected to the junction. The ringing frequency of about 90 kc is reduced by the addition of a mica capacitor C, until the saw-tooth wave is sharp with $C = 0.006$ μf as shown in Fig. 77.
Fig. 77. Ringing pictures, using 10,000-cycle saw-tooth, as capacitor C across feedback resistor is changed.

Crossover Network. These may cause oscillation if the amplifier is not stable. One sure way to know is to connect all speakers and crossovers, supply a saw-tooth source, and watch the output voltage on an oscilloscope as the controls are all turned to their maximum positions.

Wrong Power-stage Feedback. This cannot exist without damage to an amplifier or the output transducer. It can happen only in a newly constructed amplifier. A loud squawk in the loud-speaker is evidence that the amplifier is acting as an oscillator because feedback is connected in reverse phase. Removing the feedback wire and reconnecting it in proper phase may mean either a change of a primary output transformer wire or an output transformer secondary wire, depending on how the feedback is arranged.

Too Much Feedback. This usually results in a low-frequency continuous oscillation. Remedy is to use less feedback, more resistance in the negative feedback loop from output to input. Positive and negative feedback have their places in special applications.[1] In general, negative voltage feedback is the rule,[2] although negative current feedback is sometimes employed (see Fig. 29).

Insufficient Decoupling between Stages. This produces a frequency so low that it may be inaudible, or it may be a "putt-putt" motorboat sound. This will show on an output voltmeter, and if the loud-speaker cone is not concealed, the cone can be seen to move in and out slowly. More series resistance and more shunt capacitance in the plate power supply are indicated. Two stages of RC-coupled tubes fed from a common positive source of voltage cannot regenerate. The normal result is more hum when the capacitance is inadequate. But for three stages, adequate decoupling is needed. A larger series resistor or a larger capacitor to the input-stage voltage supply is usually the answer.

CHAPTER 16

ELECTRONIC OSCILLATORS

By J. K. Clapp, Frank D. Lewis, Robert A. Soderman, and Richard W. Frank[1]

Electronic oscillators are energy-conversion devices which draw electrical power from a d-c source and convert it into electrical oscillations. The oscillations so generated are alternating currents of a large variety of frequencies, wave forms, and power levels. In this chapter are discussed electronic oscillators generally, including oscillators using vacuum tubes, gas-filled tubes, and transistors as the energy converters. In addition, certain oscillators of the atomic and molecular type are included,
Fig. 1. Tuning ranges commonly afforded by adjustable tuning elements.

and some mechanical-electric systems having properties paralleling those of vacuum-tube oscillators.

Most electronic oscillators consist of a negative-resistance device and a control system including frequency-determining elements and amplitude-regulating elements. The negative-resistance device is usually an amplifier with the output coupled back to the input through the control system in the necessary manner to produce oscillations. The principal exceptions to this general rule are the atomic and molecular oscillators which may produce oscillations without this particular feedback circuit.

[1] General Radio Company.

The versatility of the electronic oscillator is evident in the wide frequency range covered and in the facility with which the wave forms desired can be produced. The most nearly constant frequencies are produced by electronic oscillators, and also frequencies which can be varied at will over wide ranges. Further discussion of the properties of electronic oscillators is given below, with references to the literature.

The chart of Fig. 1 lists the several types of oscillators discussed in this chapter arranged according to suitability of application and showing the general frequency coverage of each type.

VIBRATOR-CONTROLLED OSCILLATORS

In this section are grouped the oscillators capable of the greatest frequency stability. Each of these oscillator systems or circuits makes use of a vibrating system or device exhibiting a strong resonance at some particular frequency.

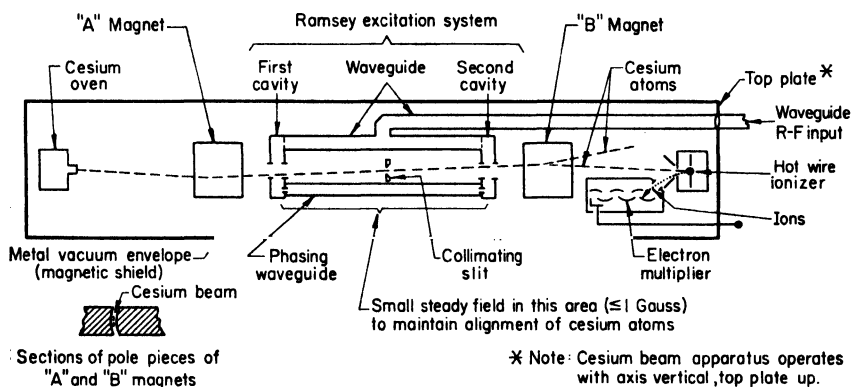
1. Atomic Resonance. The frequencies peculiar to the atoms of matter are thought to be fundamental constants of these atoms. In particular, the relationship $\epsilon = h\nu$ relates the energy ϵ involved in the change of the energy state of an atom when it


FIG. 2. Cesium atomic-beam frequency-standard apparatus.

absorbs or radiates a frequency ν. The symbol h represents Planck's constant (6.554×10^{-27} erg-sec). The absorption or radiation of energy by an atom is a quantum phenomenon, as there exists in each atom the possibility of only certain discrete states of energy. If r-f energy is coupled to atoms of a given substance at a frequency corresponding to one of the energy-level transitions permissible in those atoms, energy will be absorbed from the r-f field, resulting in the transition of some of the atoms to energy-level states higher than they occupied before the exposure to the r-f field. A number of methods have been devised for the recognition of such energy transitions in atoms.

One device which has been applied most successfully to the detection of atoms in various energy states is the *atomic-beam* apparatus. This apparatus using cesium atoms has been used as a frequency standard[1] (see Fig. 4).

The cesium-beam apparatus functions as follows: Cesium atoms are evaporated thermally from the source at the bottom and pass through the apparatus from bottom to top. The beam is operated vertically to avoid deflection of the atomic beam by gravity. The cesium atoms exist in two different energy states recognizable by the direction of deflection of the atoms as they pass through a magnetic-field gradient perpendicular to their line of travel. Atoms in one state will be deflected to the left by the magnetic gradient while those in the other state will be deflected to the right. Both magnets are oriented in the same way so that an atom remaining in the same energy state at the B magnet as it was at the A magnet

[1] Lewis, F. D., Frequency and Time Standards, *Proc. IRE*, **43**, 1046, September, 1955.

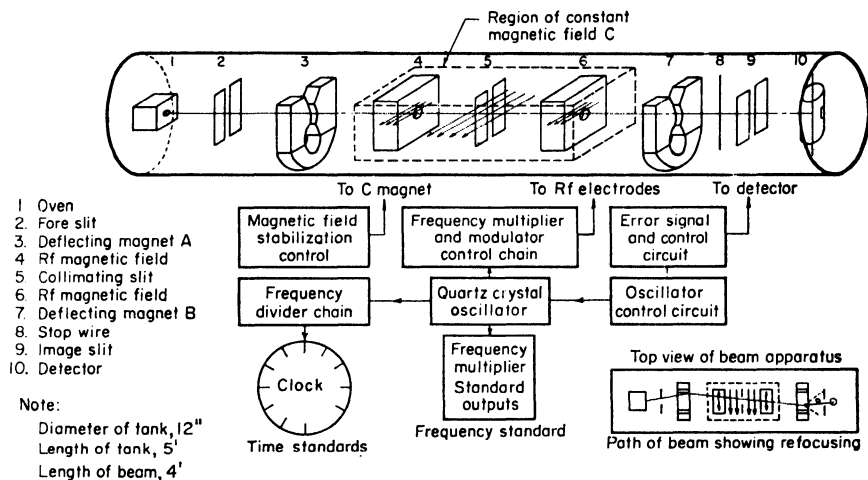
would receive two deflections in the same direction and miss the detector. However, if the atom changes its energy state between the two magnets, its deflection will be of opposite sign at the top magnet, and the atom will be deflected so that it hits the detector. A cesium atom can be made to change its energy state by adding or subtracting a quantum of energy of the correct value. This can be accomplished by passing the atom through a magnetic field oscillating at exactly the correct frequency, which is approximately 9,192.387 Mc for cesium. The cesium-beam apparatus shown uses a two-cavity, or Ramsey, excitation system which increases the resolution of the over-all system with respect to frequency. The atoms which have changed state are received at the detector, which, in one form, consists of a hot-wire ionizer and electron multiplier of the secondary-emission type. The number of atoms influenced by the r-f field is a function of the oscillation frequency, the number being greatest when the frequency is exactly equal to the required frequency for the quantum of energy needed to make the atom undergo a transition from one energy state to the other. The use of the divided excitation system produces an interference effect in the absorption of energy by the atoms, evidenced by a sharpening


FIG. 3. Schematic of atomic-beam clock and frequency standard developed at National Bureau of Standards Boulder Laboratories.

of the main peak of detector current accompanied by the appearance of "side lobes" as the frequency of excitation is varied slowly about the correct value.

It is possible to apply servosystem techniques to the cesium-beam apparatus to provide automatic frequency control of the r-f source, and thus develop a frequency standard from the atomic cesium resonance. One such system makes use of a crystal-controlled oscillator in the h-f band followed by a multiplier and a frequency synthesizer to produce the nominally correct frequency at the 9,192-Mc level. Inserted in the multiplier chain is a phase modulator, which, when followed by a large multiplication ratio in the multiplier chain, produces an f-m signal sweeping across the cesium resonant frequency. If the deviation is symmetrical about the resonant frequency, the detector current will contain only second-harmonic components of the modulation-ratio frequency, but if the deviation includes a fixed-error term, a fundamental-frequency component will appear. The phase and magnitude of the fundamental modulation-frequency component in the detector current are used to control a servosystem to maintain the r-f source on the correct frequency.

Other atomic resonances are thought to be suitable for similar applications, notably the resonances of those atoms having, like cesium, only one electron in the outermost shell. The great interest in atomic and molecular resonances stems from the belief that they represent constant-frequency references unaffected by astronomical phenomena.

2. Molecular Resonance. Since the variety of molecules is infinitely greater than that of atoms, one might be led to speculate that it would be easy to find a molecule with a convenient quantum absorption frequency and other properties making it possible to use such a molecule as a resonator for an electronic oscillator. Although much is now known[1] of the microwave spectroscopic properties of molecules, the choice of a suitable molecular resonance is difficult and the application of such a resonance is subject to many difficulties.
FIG. 4. Block diagram of National Company Atomichron cesium oscillator.

The most attractive molecule appears to be ammonia, from a microwave-resonance standpoint. Much fundamental work on microwave absorption has been done on ammonia,[2] and several methods have been devised for using the ammonia resonance at approximately 23,870 Mc for frequency standardization.

The first method to be applied practically[3] employed ammonia absorption in a wave-guide container. The r-f energy traversing an ammonia-filled wave guide was frequency-modulated so that it swept across the absorption frequency of the ammonia. As the ammonia absorbed energy, it reduced the energy received at the receiving end of the wave guide, and an absorption "pip" was produced which could be used to aid in adjustment of the oscillator frequency to keep the oscillator centered on the ammonia absorption. Fairly extensive investigation of this method for using ammonia has been carried out. Practical difficulties have restricted the stability of such systems and have led to continued

research in attempts to overcome the inherent difficulties of this system. The difficulties arise from Doppler effect and collision broadening of the absorption line and signal-to-noise ratio troubles which are linked to saturation effects.

A simpler method[1] using an ammonia-filled resonator in a Pound-type stabilizer system has been used, but it also is subject to the inherent difficulties of the absorption scheme.

A relatively recent development has enabled the use of the ammonia gas itself to produce amplification by what is known as stimulated emission of radiation. Devices of this sort are called *Masers*[2] (from the initial letters of *M*icrowave *A*mplifier by *S*timulated *E*mission of *R*adiation). An oscillator making use of this principle (see Fig. 5) consists of a source of ammonia which provides a stream of gas molecules traveling through the focusing electrodes
FIG. 5. Ammonia oscillator of Townes.

into a cavity resonator tuned to the ammonia frequency. As the molecules go through the focuser, those in the lower energy state are diverged and those in the upper state are converged and focused at the resonator. When the molecules go inside the resonator, they are acted upon by the electric field in the resonator, since the ammonia molecule in the upper (inversion) energy state has an external electric dipole moment. Noise energy in the resonator thus triggers the ammonia molecules to cause them to emit quanta to the field in the resonator, the molecules then undergoing transition to the lower energy state by the emission of the quanta. Since the molecules themselves emit the power, and since the trigger mechanism is linked directly to the phase of the r-f field acting on the molecules, the process produces a phase-coherent field in the cavity. The amount of power produced by an oscillator of this sort is very small, being estimated at 10^{-9} watt. The frequency stability is relatively high. It is expected that this type of ammonia oscillator will become useful as a frequency standard.

Although most of the work on molecular resonances for frequency control has been done on ammonia, other molecules may prove useful in this respect.[3] Detection of

hydrogen radiation from extraterrestrial sources has spurred investigation of microwave-energy transitions in gases of many different varieties, and may lead to discovery of further useful microwave-energy-transition levels of this sort.

CRYSTAL-CONTROLLED OSCILLATORS

3. Piezoelectric Crystals. No attempt will be made here to cover, even briefly, the very broad fields of crystallography and piezoelectric crystals. A comprehensive treatise is W. G. Cady's book "Piezoelectricity."[1] References on the processing and applications of quartz crystals which are very useful are those of Mason,[2] Heising,[3] Vigoreux,[4] D'heedene.[5]

Because of its availability, suitable mechanical properties, and reasonable cost, quartz is utilized almost entirely in producing crystals for frequency-control purposes.

The natural crystals rarely show a complete crystal form, which in quartz is a hexagonal prism with pyramidal ends. If the cap faces are present, visual inspection discloses whether the crystal is "right-" or "left-hand," meaning the sense in which the crystal rotates the plane of polarization of light passed through the crystal in the direction of the optic axis. If the crystal is broken, or worn, as in "river" quartz, elaborate testing is required to establish the handedness and the directions of the axes.
Fig. 6. Illustrating that the "axes" are directions in quartz.

The "axes" in crystals are not components of a fixed reference frame but are *directions* in the quartz. In Fig. 6, at any point on the crystal section, the direction perpendicular to the surface of the section (*i.e.*, perpendicular to the plane of the paper) is the "optic axis." At such a point, the direction parallel to X_1 is an electric axis, and so on.

A plate cut with its faces perpendicular to the direction X_1 would be an "X-cut" plate, no matter where located in the section, as at A, B, etc.

If such a plate is etched, then observed in a microscope, the surface toward the arrow of X_1 shows one kind of pit pattern, while the surface away from the arrow of X_1 shows an entirely different pit pattern. This is a visual demonstration of the fact that the crystal shows a polarity and that one end of the electric axis is positive while the other is negative.

By virtue of the "piezoelectric effect," if a quartz crystal is put in compression or in tension, electric charges will be developed on certain faces. Conversely, if these faces are charged, then an elongation or contraction of the quartz will result. By use of a vacuum-tube amplifier, a voltage developed on the electrodes by vibration of the plate is amplified and fed back in step so as to maintain the crystal vibration. The coupling between the mechanical system of the vibrator and the electrical drive system is extremely small. Even so, care must be taken to limit the drive on the crystal lest the crystal be fractured because of the extremely small internal losses in quartz. The equivalent electric circuit of a crystal was described by Van Dyke[6] and Mason.[7] In Fig. 7 the branch $L_1C_1R_1$ represents the motional impedance of the vibrator, where L_1 is proportional to the mass, C_1 to the elastance, and R_1 to the dissipation. C_0 represents the static capacitance of the quartz between the electrodes.

[7] Mason, W. P., *Proc. IRE*, **23**, 1252, 1935.

The ratio C_1/C_0 represents the ratio of energy stored in the mechanical to that in the electrical system.

The simplest cuts are the X-cut and Y-cut plates as at A and C, respectively, in Fig. 6. The X-cut plate vibrates in a *thickness extensional mode*, where the large surfaces of the plate alternately move apart or come together. The Y-cut plate vibrates in a *thickness shear mode*, where the upper surface alternately slides one way, then the other, while the lower surface moves similarly but in the opposite direction.

Fig. 7. Quartz plate equivalent circuit.

4. Temperature Coefficient. X-cut plates have temperature coefficients of frequency which lie in the range of -5 to -25 ppm per °C, while the Y cuts range from $+25$ to $+100$ ppm. Making a cut at some angle between the two will not yield a zero temperature coefficient because of the different modes of operation.

Development of low-temperature-coefficient quartz crystals has extended over the whole period of use of quartz plates. The history and the properties of the various cuts are well covered in Cady's book.[1] Basic coverage on low-temperature-coefficient crystals is given by Lack, Willard, and Fair.[2]

As a matter of fact, only one crystal cut can in any truth be claimed as a "zero-temperature-coefficient" cut, that is, the GT cut.[3] When properly made it has

Fig. 8. Temperature dependence of various crystal cuts. (*From Bell System Tech. J.*)

a very small temperature coefficient over a wide temperature range, 0 to 100°C. All other "zero-temperature-coefficient" crystals have parabolic characteristics such that, at the "turn-over" point, the slope of the frequency-temperature curve is zero. At this point, no change in frequency occurs over very small changes in temperature. In other words, the crystal has a zero temperature coefficient of frequency *at a single temperature only*, as is easily seen in Fig. 8.

The commonly used quartz plates, having zero temperature coefficient of frequency at a single temperature, are "rotated Y-cut" plates, where one edge is in the direction of the X axis, and the other, instead of being in the direction of the Z, or optic, axis,

[3] Mason, W. P., A New Quartz Crystal Plate, Designated the GT, Which Produces a Very Constant Frequency over a Wide Temperature Range, *Proc. IRE*, **28**, 220, May, 1940.

makes an angle with it. There are two angles, one positive and one negative, where zero-temperature-coefficient plates result. It is interesting to note that these angles are related to the minor rhombohedral faces of the crystal pyramidal cap, and that the plates are cut approximately parallel with these faces, as can be seen from Fig. 9.[1]

The temperature at which the turn-over point occurs is a very critical function of the angle at which the plate is tipped away from the Z axis. If uniform performance
Fig. 9. Types of crystal cuts. (*Modified from Heising, "Quartz Crystals for Electrical Circuits."*)

of these crystals is required, continuous checking of the angle of tilt must be carried out during processing. It is not sufficient to test the angle of a blank, for example, and assume that the angle will be maintained as the crystal is ground to frequency.

The thickness-shear mode AT and BT crystals are widely used for frequencies above 500 kc. These crystals can be used in overtone modes giving substantially higher frequencies—up to 250 Mc or more.

5. Overtone Operation. The mechanism of overtone operation is illustrated in Fig. 10. In *a* the fundamental mode is shown, where the displacement resulting from charging the electrodes is shown. If a suitable circuit is used, the thickness of the crystal can be made to vibrate in several sections, as in Fig. 10, where five

[1] Koga, Isaac, *Proc. IRE*, **24**, 510, March, 1936.

sections are illustrated, each of one-fifth of the thickness, and consequently the frequency will be five times as high. The overtone frequencies are not *exact* multiples of the fundamental frequency but are very nearly so.

It is evident from the figure that the electrodes are such that the polarity of the crystal slabs must always agree. If an even number of slabs existed, the top and bottom faces would be of like sign and no excitation would be possible. Consequently only odd overtones can be excited.

The shunt capacitance of the quartz imposes a limitation on how high an overtone can be used successfully in an oscillator requiring the crystal to present an inductive reactance. By means of a special holder, which in effect provided a capacitance bridge to neutralize the shunt capacitance, overtones as high as the twenty-third have been used. A parallel-tuned circuit placed across the crystal and tuned to the desired overtone frequency accomplishes a similar purpose.

FIG. 10. Fundamental and overtone operation.

6. Crystal Mounting. The mounting of a quartz plate is most important in determining its performance. Quartz plates for the most accurate requirements are now made with lens-shaped instead of flat surfaces. The central area may or may not be flat and is the area where the electrodes are plated. The edges of the crystal, if it is of proper size for the frequency required, are nearly quiescent so that attachment of the mounting and connecting wires does not appreciably disturb the vibration. As there is no motion at the edges, no energy from the vibrating portion is lost through the supports.

The crystal mount is placed in an evacuated glass bulb which not only eliminates losses caused by ultrasonic radiation into the air, but also prevents air loading, contamination, moisture, etc., from affecting the crystal.[1]

An extensive study of quartz plates by Bömmel, Mason, and Warner[2] answers many questions which heretofore have apparently had no or, at most, ambiguous answers. The performance of plates in air (or inert gases) differs considerably from that in vacuum. Conclusions arrived at in the first case do not apply in the second.

For 15-mm-diameter contoured quartz plates in vacuum, the following may be concluded:

1. Q is greater by three times than in air.
2. Q is no longer a function of the overtone (or thickness) of the plate. Observations on 10-Mc plates at the third, fifth, and ninth overtone, giving 3:1 difference in thickness and 27:1 difference in equivalent L and R, showed the same Q at all overtones.
3. Q does not change with plating thickness in a 3:1 range.
4. Carefully polished surfaces yield Qs no more than 10 per cent above those obtained with carefully lapped and etched surfaces.
5. Above 30 Mc, evacuation produces no measurable increase in Q.
6. At 100 Mc, the best Q is about 150,000.

Low-temperature Quartz Crystals. The internal loss $1/Q$ increases as the temperature is reduced down to 52°K, where a sharp internal friction peak occurs. The loss then decreases, rises again to a broad lower peak around 21°K, then decreases to a value of 2×10^{-7} at 6°K and remains constant down to 1.5°K (lowest temperature reached). The constant loss has been ascribed to mounting loss. The indicated relaxation frequency at room temperature is about 160 Mc.

This agrees with experience that the Q of quartz plates decreases as the frequency increases. Beyond 160 Mc, the Q should begin to increase as the frequency is increased.[3]

If crystals are operated at liquid-hydrogen temperature (4.3°K) the Q of an AT-cut 5-Mc crystal is at least twice that at room temperature and aging is greatly reduced. The temperature coefficient of frequency is $0.01/10^6/°K$. Indicated stabilities of 1 in 10^{11} are possible.

[2] Bömmel, H. E., W. P. Mason, and A. W. Warner, Dislocations, Relaxations and Anelasticity of Crystal Quartz, *Phys. Rev.*, **102** (1), 64–71, 1956.

[3] George, W. D., Frequency Standard at Low Temperature, *Proc. 10th Annual Symposium on Frequency Control*, May, 1956, p. 197. Searles, C. E., R. A. Sykes, and I. E. Fair, "Information Bulletin on Quartz Crystals," Armed Services Electro Standards Agency, Fort Monmouth, N.J.
If the decrease of aging follows the increase in time of chemical reactions, the aging of a quartz plate would be reduced by a factor of the order of 10^{10}. The aging in 40 years at low temperatures would be less than that in 1 sec at 50°C.

The writers[1] conclude that the best frequency for frequency-control purposes is a function of the size of quartz plate available. For 15-mm-diameter plates, the best frequency is approximately 5 Mc. Tests with 30- and 90-mm-diameter plates show the Q at 1 Mc is not degraded by loss of energy at the edge of the plate in these larger sizes. Maximum Q is about 10×10^6.

7. Essen Ring. A form of quartz crystal for low-frequency precise standards giving excellent performance is the Essen ring.[2] The ring is 90 mm in diameter and vibrates in an extensional mode of six sections. The ring is supported on threads touching the ring at points 120 deg apart.

The frequency of oscillation is a function of the mean diameter, which probably accounts for the very small aging observed. If material is lost from the surfaces, the loss on the outside is nearly balanced by the loss on the inside, so that the frequency change is very substantially less than in more usual types.

The crystal has a temperature-frequency curve similar to that of bars, and by choice of the dimensions of the cross section the temperature of the turn-over point can be controlled.

8. Servocontrolled Piezoelectric Oscillators. A crystal oscillator circuit providing unusual means for ensuring that the crystal is the principal frequency-controlling element is the servocontrolled oscillator of Lea,[3] of which a variation is that of Sulzer.[4] In Fig. 11, a Gouriet-Clapp oscillator is shown modified to include the servocontrol circuit. A bridge is constructed by adding a resistor R_1 in series with the crystal and adding two more arms of R_2 and R_3 and X, with R_2 and $R_3 \gg R_0$ to minimize shunting effects on the crystal branch. The reactances X are arranged to be differentially modulated by a modulating device which is a part of the servosystem. By arranging for the output of the a-m detector on the bridge to be compared with the modulation amplitude and phase of the modulating device, the sense and magnitude of the bridge unbalance are measured and used to control a servodrive which readjusts the oscillator circuit to restore the frequency for which the bridge has no reactance unbalance. The bridge is set up to balance initially for the resistance values chosen. Hence the bridge balance is a function of the frequency of the driving source only, balance being obtained at series resonance of the crystal. This system provides
FIG. 11. Servocontrolled oscillator, a modification of the Gouriet-Clapp circuit.

correction for any variables affecting the oscillato frequency, which is the frequency of the signal applied to the crystal bridge circuit, in so far as the servo ystem can correct for these variables. There is always a small residual error in a servosystem, but by the provision of a large amount of gain in the detector device, a large amount of correction can be obtained. One of the important properties of this circuit is that the added stabilization system does not work at the crystal frequency but at a fixed frequency in the a-f range (the modulation-rate frequency) and hence is useful for stabilizing crystal oscillators in the h-f and v-h-f regions as well as in the m-f and l-f bands where conventional negative-feedback stabilization of amplifiers is most effective. Also, it is possible to correct for such items as cathode-interface impedance by this method.

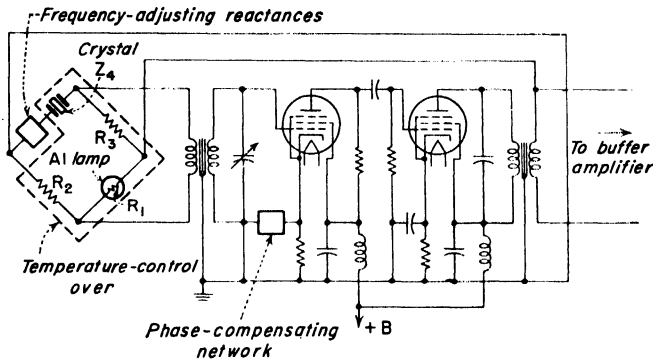
Lea applied this circuit to a 5-Mc oscillator using a rotating-toothed-wheel inductance modulator for reactance variation and obtained stabilities of 1 part in 10^{10} or better when tubes were changed and supply voltages varied over wide ranges. The crystal frequency for series resonance is thus used as the reference for the servosystem to provide improvements of 10^4 or 10^5 in over-all long-term stability. The short-term, or phase, stability of the oscillator is determined by the crystal, the effective Q of


FIG. 12. Meacham's bridge-stabilized oscillator.

which has been degraded to one-half its original value by the addition of the resistor R in series with the crystal.

9. Conventional Piezoelectric Oscillators. In Lea's oscillator, described above, the only variation in frequency which can occur is that caused by changes in the constants of the reference crystal itself. Such changes would result in a change in the frequency at which the reference phase occurs.

In conventional circuits, changes in frequency result from any changes in the constants of the crystal but also from any changes in circuit reactances. Changes in the constants of the vibrator can result from the gradual relief of strains in the quartz, exposure to contaminating influences, chemical or physical changes in the plating on the surfaces, migrations of metals involved in the plating or soldering of supports, changes in the supports, and loss of material from the surface of the quartz.

Changes in circuit reactances can result from aging of vacuum tubes, development of cathode-interface impedance, changes in electrode voltages, changes in tube structure with temperature or time, changes in operating level, and a variety of other factors.

10. Driving Circuits. The Meacham[1] oscillator in Fig. 12 represents a high degree of development in making the oscillator frequency nearly independent of the driving circuit. The frequency variations remaining, though small, are none the less troublesome for the most precise requirements, and considerable effort has been expended in still further reducing them.

[1] Meacham, L. A., The Bridge-stabilized Oscillator, *Proc. IRE*, **26** (10), 1278, October, 1938. Also *Bell System Tech. J.*, **17** (4), 574.

One approach was that of Lea, whose oscillator has been described above. The U.S. Bureau of Standards eliminated the driving circuit entirely, using the quartz crystals as resonators only. This is satisfactory as a reference standard but does not yield a working frequency standard.

In spite of their defects, conventional crystal oscillators are still our working tools. A thorough understanding of the operation of the circuits will, in time, lead to still further improvements in performance.

11. Meacham Oscillator. Fundamentally, this is a tuned pentode amplifier with the output stepped down to a low-impedance bridge by the tuned output transformer. The bridge contains the quartz crystal and a small lamp, which is the means for regulating the operating level, in two of the arms. The other two arms are resistors. The bridge output is stepped up through a tuned input transformer to the grid of the pentode amplifier.

The bridge arms are arranged so that, when oscillation starts, the lamp filament is cold, with the lamp resistance at a low value, and the bridge is unbalanced in such a way as to produce a large output voltage from the bridge in a sense to give positive feedback. The amplitude of oscillation builds up rapidly and the lamp-filament temperature rises quickly. As the lamp resistance increases, the bridge approaches, but never quite reaches, balance. The bridge output voltage is thus reduced to a very small value, which stabilizes at the level where the loss through the bridge is just equal to the gain through the amplifier back to the bridge input. Large changes in bridge loss result in minute changes in input level; the bridge therefore is a most effective automatic level control.
FIG. 13. Modified Meacham oscillator.

The arms of the bridge are intended to be nonreactive. This means that the crystal must operate at zero reactance, which, for low-frequency crystals such as those commonly used in primary frequency standards, is very nearly at series resonance.

Meacham gave an analysis of the operation of the bridge oscillator in which considerable emphasis was placed on the effective cancellation of the resonator resistance by the balancing of the bridge. This results in an enhanced slope of the phase characteristic of the bridge output, which led to the popular statement that "the bridge multiplied the Q of the crystal."

The use of two tuned transformers makes Meacham's circuit difficult to adjust and more sensitive to variation in circuit parameters than it need be. For greater simplicity in operating with crystals of different frequencies, a circuit was proposed[1] using only one tuned circuit (Fig. 13). In adjusting this circuit, if means are available for phase indication, the tuning can be set easily and accurately by phase rather than by amplitude indications.

Post and Pit[2] point out that other viewpoints are equally valid. They also contribute a most important factor in analysis of the oscillator. This is that, while attention has been almost exclusively directed (most especially in the United States) to improvement of the quartz resonator to obtain higher Q, equally important gains

[1] Clapp, J. K., An Analysis of the Bridge-controlled Oscillator, *Gen. Radio Experimenter*, May, 1944.

[2] Post, E. J., and H. F. Pit, Alternate Ways in the Analysis of the Feedback Oscillator and Its Application, *Proc. IRE*, **39** (2), 169, February, 1951. Cady, *op. cit.*

are possible by improvement of the driving amplifier circuit. The stability of the oscillator depends on the *ratio* of resonator phase slope to amplifier phase slope, and making the amplifier phase slope *effectively zero over the very limited required frequency range* is just as important as obtaining the *greatest possible phase slope in the resonator.*

12. One-tube Oscillators. A general-purpose and simple piezoelectric oscillator is a one-tube circuit which is the basis of the so-called "series-tuned" circuits. A diagram is given in Fig. 14*a*. The reactances of C_1 and C_2 are made as low as possible
Fig. 14. General-purpose crystal oscillators. (*a*) Series-resonant crystal; (*b*) crystal adjusted to work with specified value of series capacitor *C*.

while still permitting oscillation. If frequency adjustment is desired, a reactance can be placed in series with the crystal, usually a small capacitance. The crystal must then be ground so its natural frequency is slightly low, and the value of series-capacitance must be specified. Several values of capacitance are used as "standard," 32 $\mu\mu$f being used most frequently.

A better system is to use an inductive and capacitative reactance in series, of such values that, if the crystal is replaced by a resistor, the frequency of oscillation is the same as the crystal frequency. The crystals would then be ground as "series-resonant" (Fig. 14*b*).
Fig. 15. Crystal oscillator circuits.

The older piezoelectric oscillators are little used today. The early forms developed by Cady, Pierce, and Miller are shown in Fig. 15, and are described by Cady.[1]

In *Cady's circuit* the crystal acted as a coupler between output and input of the amplifier, where a voltage appeared at the grid as a result of the mechanical vibration produced by the electrodes connected to the plate circuit. Variations of this type of crystal are now used in filters rather than in oscillators.[2]

In *Pierce's circuit*, the crystal is connected between grid and plate, and a resistor or choke coil is utilized in the plate circuit, later replaced by a tuned circuit. This is a *Colpitts circuit* with the tube capacitances acting as the circuit capacitances and the crystal operating above its resonant frequency to provide an inductive reactance.

[1] Cady, *op. cit.*, pp. 286, 494.

[2] Post, E. J., and J. W. A. Van der Scherr, Bridge Stabilized Oscillators and Their Derivatives, *Het P. T. T.*, Bedrijf, **6** (4), 86, September, 1944.

In the *Pierce-Miller circuit*, the crystal is connected between grid and cathode, and a tuned circuit is used in the plate circuit with the plate tapped down to improve the power output. Here the grid and plate impedances are inductive, the crystal operating above resonance, and the grid-plate tube capacitance completes the oscillating (Hartley) circuit.

Neither the Pierce nor Pierce-Miller circuits can operate at the resonant frequency of the crystal, and the nearer to the resonant frequency they are adjusted, the more unstable and critical they become.

The "series-tuned" type of Fig. 14 is much to be preferred.

Phase-locked quartz-crystal oscillators can be used to great advantage in frequency multipliers.

OTHER VIBRATOR-CONTROLLED OSCILLATORS

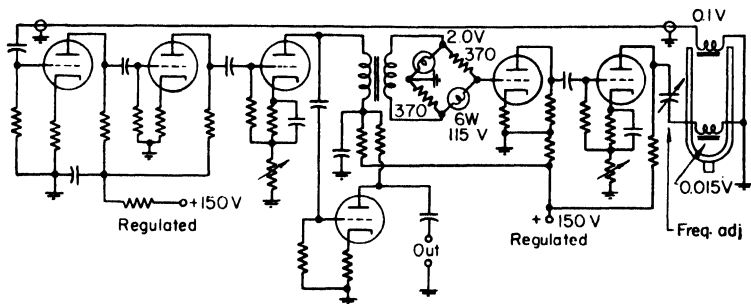
13. Tuning-fork Oscillators. Vacuum-tube-driven tuning forks are useful for frequencies from 50 cycles up to a few thousand cycles. The principal advance over the years has been in the very substantial decrease in the temperature coefficient of frequency of the fork. The design first utilized a bimetallic fork where the heel of the fork was of one alloy and the end portions of the tines were of another alloy.
FIG. 16. Tuning-fork oscillator.


FIG. 17. Amplitude-regulated fork oscillator.

Later developments brought out the "sandwich fork" where the basic fork was of a uniform material. To correct the temperature coefficient, a thin slice of a different alloy was bonded on one side of the fork. This gives a structure which can be *adjusted* for temperature coefficient by grinding either the basic fork or the sandwich layer. Temperature coefficients of frequency less than 1 ppm per °C can be obtained in production.

The drive of precision forks is generally by electromagnetic excitation and pickup, as indicated in Fig. 16. Most fork oscillators have no provision for amplitude control, other than amplifier limiting. Improved performance can be obtained by use of

amplitude control, shown in Fig. 17. Fine adjustment of frequency can be made by phase control in the oscillator circuit.

14. Magnetostriction Oscillators. Of late years not much attention has been given to magnetostriction resonators, principally because of the comparatively high temperature coefficient of frequency. The rod alloys have a bearing on this coefficient, and searching for "zero temperature coefficient" is most disappointing because just as one creeps up on that most desirable state, the activity reaches zero first. Nature can be so contrary! A comprehensive paper was given by Pierce[1] discussing oscillator circuits and various magnetostrictive alloys.

The circuit for a magnetostriction oscillator is very simple, the principal variation being that the coupling is reversed in comparison with the usual oscillator (Fig. 18).

FIG. 18. Magnetostriction oscillator.

The frequency range of magnetostriction oscillators is from several hundred cycles to several tens of kilocycles.

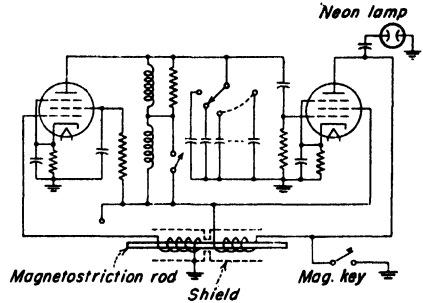
15. Pendulum Oscillators. Oscillators operating at very low frequencies can be stabilized by the use of pendulum resonators. The most highly developed forms of precision pendulum clocks[2] make use of electric impulses to drive a free pendulum in an evacuated chamber, related electric impulses being used to drive a slave clock with indicating mechanism. When the pendulum swings at a very small and constant amplitude in an evacuated chamber, the oscillation time is approximately $T = \sqrt{l/g}\,(\sin \theta)/\theta$. Enough energy is added on each swing, at the point of maximum velocity, to make up for loss in the supports. Constant-period oscillations result from this method of operation.

The Shortt and Riefler clocks which have been used as observatory time standards are made in the manner described above. Stabilities of the order of 1 part in 10^7 were not unusual for these clocks although they were affected by changes in the gravitational constant and by vibration of their mountings. Extreme care is necessary in the installation of such clocks to provide solid vibration-free installations in constant-temperature surroundings.

The contacts used on the clocks for controlling the impulse drives were mechanical in nature. Other means can be used such as photoelectric devices, or inductive or capacitive pickup systems. These systems would require the use of amplifiers to ensure proper functioning.

LC OR RESONANT-CIRCUIT CONTROLLED OSCILLATORS

16. Frequency-stable Oscillators. Here are emphasized those circuits intended particularly for uses where frequency variations caused by the driving tube are to be reduced to a minimum. Typical applications are as master oscillators in transmitters, heterodyne-frequency meters, beat-frequency oscillators, and finely and accurately adjustable frequency sources.

Over a period of two decades, workers in various parts of the world have attacked this problem; all have obtained the same basic result. To keep discussion within reasonable limits, assume the following restrictions:


[1] Pierce, G. W., Magneto-striction Oscillators, *Proc. Am. Acad. Arts Sci.*, **63**, 1–47, 1928. Also *Proc. IRE*, **17**, 42, 1929.

[2] Marrison, W. A., The Evolution of the Quartz Crystal Clock, *Bell System Tech. J.*, **27**, 510, July, 1948. Also published as "Bell Telephone System Monograph B-1593," Bell Telephone Laboratories, and in *Horological J.*, **90**, 274, May–October, 1948.

1. Frequency stability shall apply only to those effects produced by the driving-tube amplifier, due to (1) changes in tubes, (2) changes of electrode voltages, (3) mechanical changes with time, (4) temperature, or (5) changes in operating level.

2. The changes in the frequency-determining resonant circuit caused by mechanical displacements, temperature, pressure, humidity, and time are a completely separate problem which will not be discussed here.

The principles independently arrived at for a basic frequency-stable LC oscillator are simply stated:

1. Use a high-quality tuned circuit (high Q).
2. Use a "series-tuned" circuit, which is equivalent to tapping the vacuum-tube input and output across as low impedances as possible in the tuned circuit, while maintaining oscillation.
3. Use an external system of automatic level control, keeping grid and plate swings of the oscillator tube to a volt or so and grid current at zero.
4. Choose a tube having a low $\Delta C/g_m$ ratio.
5. Operate the vacuum tube in as linear a region of its characteristic as possible.

Brief comments on these points follow:

1. In familiar LC oscillator circuits, such as the Colpitts and Hartley, the tube impedances are low, and they are connected across impedances in the LC circuit many times higher in magnitude. The "loaded" Q of the circuit is then only a fraction of the natural or "unloaded" Q, so that any benefits derived from a high-Q circuit are completely wiped out.
2. If an oscillator circuit, no matter how good it may be in circuit design, is poorly constructed, the frequency stability will be poor. Good mechanical design is as important as good circuit design.
3. The *series-tuned oscillator* is defined as follows: an oscillator in which the input and output circuits of the tube amplifier are connected across very low reactances in the tuned circuit, and in which the feedback path from output to input is through *a series-tuned circuit, the reactances of which are substantially greater than those across which the vacuum-tube circuits are connected. The frequency of oscillation is close to the resonant frequency of the series-tuned circuit.*
4. Many writers have chosen to use a tube of the highest possible g_m, even placing tubes in parallel to increase the value of g_m, *based on the assumption of a specified change in, say, tube input capacitance.* In the actual circuit, the change in grid-cathode capacitance is a property of the tube, and in general it is greater in high-g_m tubes than in other types. If tubes change their input capacitance by a given percentage, then least capacitance change takes place in the tube having the lowest input capacitance. The g_m of the tube determines the minimum magnitude of the coupling reactances, which in turn define the factor by which the resulting frequency change is reduced. The tube having the least $\Delta C/g_m$ ratio will therefore give the best frequency stability against changes in tube capacitances.
5. Linear operation is a necessity to prevent frequency changes produced by generation of harmonics. Several writers[1,2] have shown that the presence of harmonics causes a phase shift of the fundamental component. Since this shift will vary with the amplitude of oscillation and the harmonic content, which can change radically with changes in operating level, it must be kept down by linear operation and by a good automatic level control.
6. From the preceding paragraph, it is evident why limiting by grid current is detrimental to frequency stability: harmonics are generated. The harmonic content changes with level, resulting in phase shifts of the fundamental.

17. Stability Considerations. A great deal of attention has been given to the question of stability of frequency of oscillators, to means for improving frequency stability by use of stabilizing reactances, and to studies of the frequency stability as a function of the circuit parameters, notably by Llewellyn,[1] Groszkowski,[2] Heising,[3]

[1] Llewellyn, F. B., Constant Frequency Oscillators, *Proc. IRE*, **19** (12), 2063, December, 1931.
[2] Groszkowski, Janusz, The Interdependence of Frequency Variation and Harmonic Content and the Problem of Constant-frequency Oscillators, *Proc. IRE*, **21** (7), 958, July, 1933.
[3] Heising, R. A., Stability in High-frequency Oscillators, *Proc. IRE*, **31**, 595, 1943.

Mallett,[1] Gladwin,[2] Lukaszewicz,[3] Beurle,[4] and Roberts.[5] Attention here will be confined to circuit arrangements giving improved frequency stability by linear operation of the tube and an accompanying means of amplitude control, rather than by use of compensating reactances.

Jiri Vackar[6] has treated the oscillatory circuit as a four-pole and given a straightforward analysis. Since this paper is not readily available to many readers, a summary covering the essential features from an engineering point of view was given by Clapp[7] and also by Edson.[8]

Basically, Vackar starts from the parallel resonant impedance R_0 of the tuned circuit and uses the fact that, when one branch is tapped at a point having a reactance X_2 to ground, the impedance across the tap to ground is $R_0X_2^2/(X_1 + X_2)^2$. Since the internal reactances of a vacuum tube are inherently capacitative over very wide ranges of frequency, it follows that, if the tuned circuit is tapped on the capacitative branch, the tube reactances are placed in parallel with reactances of like kind, leading to a number of favorable results which have been appreciated by many writers. The resonant impedance of the tuned circuit is

$$R_0 = QX_0 = \omega^2L^2/R_s = 1/\omega^2C_0^2R_s = L/C_0R_s$$

where C_0 = the net total resonant capacitance of the capacitative branch, and R_s = the effective *series* resistance of the loop. To determine the impedances Z_1' and Z_2' presented to the input and output terminals of the tube, it is necessary to know the value of R_0 and the values of the capacitative reactances determining the stepdown impedance ratio.

Fig. 19. Oscillator and equivalent. To oscillate, $g_mX_1X_2 = R_s$.

Clapp[9] presented an analysis of the input impedance of a tube, together with the associated input and output circuit reactances, showing that this combination acts as a negative resistance of value $-g_mX_1X_2$, in series with the (low) circuit reactances X_1 and X_2. If, across the grid and plate tube terminals, an inductance or an inductance and series capacitance are connected, oscillation will take place if $g_mX_1X_2 \geq R_s$ (see Fig. 19).

It is instructive to start from the parallel-resonant circuit analysis and show that the series circuit analysis can be derived directly from it.

Vackar states that the condition for oscillation is $1/g_m = \sqrt{Z_1'Z_2'}$. Applying this to the basic circuit (column 2, Table 1, page 20), we have

$$\begin{aligned}
Z_1' &= R_0(C_vC_1)^2/(C_v + C_1)^2 = R_0C_v^2/C_1^2(1 + C_v/C_1)^2 \cong R_0(C_v/C_1)^2 \\
Z_2' &= R_0(C_vC_2)^2/(C_v + C_2)^2 = R_0C_v^2/C_2^2(1 + C_v/C_2)^2 \cong R_0(C_v/C_2)^2 \\
g_m &= 1/\sqrt{Z_1'Z_2'} = (C_1/R_0)(C_1/C_v)(C_2/C_v) \\
&= R_s\omega^2C_v^2(C_1/C_v)(C_2/C_v) \\
&= R_s\omega^2C_1C_2 \\
&= R_s/X_1X_2
\end{aligned}$$

as given by Clapp, neglecting small correction terms.

Vackar's result is of engineering interest because it emphasizes the fact that the tube is connected across reactances which, as stepped down by the tapping, are *very low* compared with the resonant impedance. However, in stating his results in terms of Q, interpretation is clouded since assumption that Q varies in a certain manner or remains constant as the frequency is varied may be quite unjustified. In the series circuit analysis, the parallel-resonant impedance is of no direct interest, and Q comes into the picture only incidentally as R_s changes. There is no interest in the impedance stepdown ratio as such, since only the magnitudes of the reactances, across which the tube is connected, are involved.

The series analysis is based on the vacuum tube with the associated input and output reactances, as shown in Fig. 19.

The effect of a change ΔC_1 in the input capacitance of the tube, connected across the tapped impedance Z_1' of the tuned circuit, causes a detuning equivalent to a change ΔC_0 in the net tuned-circuit capacitance C_0 such that

$$\Delta C_0/\Delta C_1 = Z_1'/R_0 \tag{1}$$

where R_0 = parallel impedance of the tuned circuit.

If the tuned-circuit capacitance is C_0, a change ΔC_0 in this capacitance causes the fractional frequency change

$$\begin{aligned}\Delta f/f_0 &= \Delta C_0/2C_0 \\ &= (Z_1'/2R_0)(\Delta C_1/C_0)\end{aligned} \tag{2}$$

Similar considerations apply for changes in the output capacitance of the tube. For *equal* changes in *either* input or output tube capacitances, the minimum frequency change occurs when $Z_1' = Z_2' = 1/g_m$, and is

$$\begin{aligned}\Delta f/f_0 &= (1/2R_0C_0)(\Delta C_1/g_m) \\ &= (\omega_0/2Q)(\Delta C_1/g_m) \\ &= (2\pi f_0/2Q)(\Delta C_1/g_m)\end{aligned} \tag{3}$$

Frequently, the change in tube output capacitance is less than that of the input capacitance. In such cases, slightly improved stability can be obtained by making $Z_1' \neq Z_2'$. Then

$$\begin{aligned}\Delta f/f_0 &= (1/2R_0C_0)(\Delta C_1/g_m)(2/\sqrt{k}) \\ &= (\omega_0/2Q)(\Delta C_1/g_m)(2/\sqrt{k}) \\ &= (2\pi f_0/2Q)(\Delta C_1/g_m)(2/\sqrt{k})\end{aligned} \tag{4}$$

where $k = \Delta C_1/\Delta C_2$.

Equation (4) is very useful since it gives the frequency-stability coefficient immediately when the quality of the tuned circuit and the $\Delta C_1/g_m$ ratio of the tube are known.

If ΔC_1 were independent of g_m, the tube having the highest g_m would give the best frequency stability; this conclusion has been reached by several writers. In practice, however, the tubes having the larger values of g_m have also the larger values of C_1 and the larger values of ΔC_1. The choice of a tube having very low capacitance and small changes of tube capacitances associated with only moderate values of g_m will frequently result in substantially lower $\Delta C_1/g_m$ ratio with consequent improved frequency stability. This is particularly true of the secondary changes in tube capacitances such as those caused by changes in temperature of tube structure and by changes in emission of the cathodes.

Equation (4) also indicates that the frequency stability is independent of the L/C_0 ratio of the tuned circuit. The stability depends only on the quality of the tuned circuit (first factor) and, for a given value of ΔC_1, on the g_m of the tube (second factor). The latter term determines the minimum possible coupling between the driving circuit and the controlling circuit.

In Table 1, several frequency-stable LC oscillators are shown, in progressive order of adaptation of the coupling means to the tube, to give wider frequency ranges and more nearly constant amplitude over the tuning band. The equivalent circuits are shown, where a single variable capacitance is used but effectively acts as if it were a two- or three-gang unit.

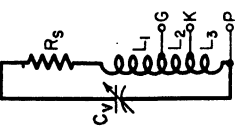
While the basic oscillation circuit is shown, details of connection to the tube are omitted. Depending upon the position of the rotor of the variable capacitor, various

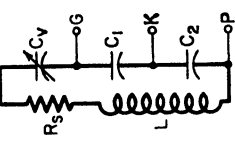
ground points may be chosen so as to ground the rotor. Frequently, a grounded-plate oscillator is desirable, since no d-c voltage then appears on the tuned-circuit elements.

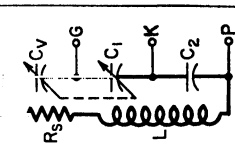
The positions of the inductor and variable capacitor can be interchanged without difficulty if advantage in grounding the capacitor results.

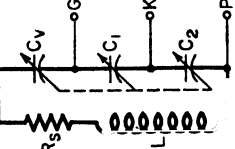
Two examples of complete oscillators are shown in the bottom of the chart; one (column 2) is a grounded-plate version and one (column 5) is a grounded-cathode circuit. In the first, the d-c voltage is removed from the tuned circuit while using series-connected plate supply. In the second the d-c voltage is removed from the tuned circuit while using parallel-connected plate supply.

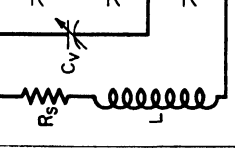
In each column, the g_m required for oscillation is given in terms of C_v, the tuning capacitance. If the required g_m decreases as C_v decreases, the amplitude of oscillation will increase as the frequency is increased. In other words, if the circuit is tuned toward lower frequencies, the amplitude decreases, and if C_v becomes large enough, oscillation ceases. Such circuits are shown in columns 1, 4, and 6. The circuit of column 2 acts in the reverse sense, with oscillation ceasing if C_v becomes sufficiently small. The circuits of columns 3 and 5 show more nearly constant amplitude with tuning.
FIG. 20. Clapp-Gouriet oscillator, a modified Colpitts.

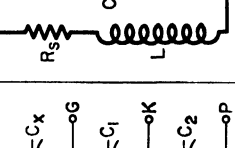
All the above statements are strictly true only when R_s remains constant over the tuning range. Since R_s can *decrease* as frequency *increases* in the low-frequency ranges (say 10 to 1,000 kc) and can *increase* in the higher-frequency ranges (say 500 kc to a few megacycles), the performance of any of the oscillator circuits can be modified appreciably. In the range from a few megacycles to several tens of megacycles, R_s generally decreases gradually as the frequency increases as long as the natural frequency of the inductance is not approached too closely.[1] The circuit of column 7 has provision for varying the coupling by a combination of variable and fixed capacitances C_2 and C_3. If C_3 is large compared with C_2, the performance is similar to that of the circuits of columns 4 and 6. If C_3 is of the same order as C_2, the performance approaches that of the circuits of columns 3 and 5. By proportioning of these two capacitances, adjustment can be made to obtain nearly constant amplitude in spite of variation of R_s over the tuning range.


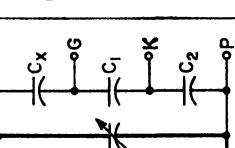












In each column, the originator is named, with references to publication. The usually effective tuning range is given at the bottom of the column.

For operation at a single frequency, or over a very limited frequency range (not greater than 1.03:1, for example), all the circuits shown, if properly adjusted, would give identical stabilities. Consequently, the simplest circuit (column 2) would be the one to use, since no advantage results from using more elements.

As the tuning range is extended, the more complicated circuits give much more nearly constant amplitude over the tuning range and the added elements are well

justified. The circuit of column 5 is first choice because a single variable element is used, which rules out the circuit of column 3.

The added complexity of the circuit of column 7 is seldom justified. It would be used only where a very wide tuning range was a prime requirement.

18. Amplitude Control. Gouriet[1] shows a simple amplitude regulator applied to the oscillator of column 1 (but a similar arrangement can be used with any of the other circuits). A resistance is added in series with the plate to provide an r-f voltage which is applied to a diode rectifier. A germanium diode could equally well be used. The rectified voltage is filtered and applied at the base of the grid resistor R_g.

A more complete circuit is shown in Fig. 21. Here, an amplifier is added to provide greater drive of the diode. With the amplifier, the circuit can maintain practically a constant and low level of about 0.1 to 0.01 volt. An output amplifier is used in
FIG. 21. Practical v-f-o oscillator for transmitter. LC_v is in a temperature-controlled space. For LC_v a crystal may be substituted with appropriate values of C_1 and C_2. Plug-in coils may be used.

practical applications. Such oscillator circuits have been used in master oscillators of transmitters. The performance attained is indicated by the following figures:

1. Plate-voltage change = ±20 per cent; Δf resulting = $\pm 2.5/10^6$
2. Filament-voltage change = ±5 per cent; Δf resulting = $\pm 2.5/10^6$
3. Stability with time

1 hr.	$\Delta f = \pm 1/10^6$
1 day	$\Delta f = \pm 10/10^6$
1 month	Δf = with reset accuracy of $\pm 30/10^6$

A sensitive means of testing or comparing LC frequency-stable oscillators to determine how free the frequency of oscillations is from any variation due to tube voltages is afforded by the locking system described in Sec. 61. Where an ordinary Hartley or Colpitts oscillator will lock over a range from several tens to several hundred parts per million, a well-adjusted frequency-stable oscillator will show no locking whatever.

19. General-purpose Oscillators. Oscillators for general application as power sources in the a-f and r-f ranges can be constructed with LC tuned circuits as the principal frequency-determining elements. The circuits shown in Fig. 22 are shown as triode circuits, but they may be used as multigrid circuits if the appropriate elements are added. Also by the use of multigrid tubes and proper circuit manipulation, each of these circuits can be changed to provide an electron-coupled output circuit. An electron-coupled Colpitts oscillator is shown at f in Fig. 22.

20. Choice of Oscillator Circuit. The actual circuit used must depend on the application for which it is intended. Several representative uses of the several oscillator circuits as shown in Fig. 22 may be of interest in helping define the field of application of the various circuits.

The tuned-grid oscillator is frequently used in radio receivers as a regenerative detector or as the local oscillator in superheterodyne receivers. It can be made to

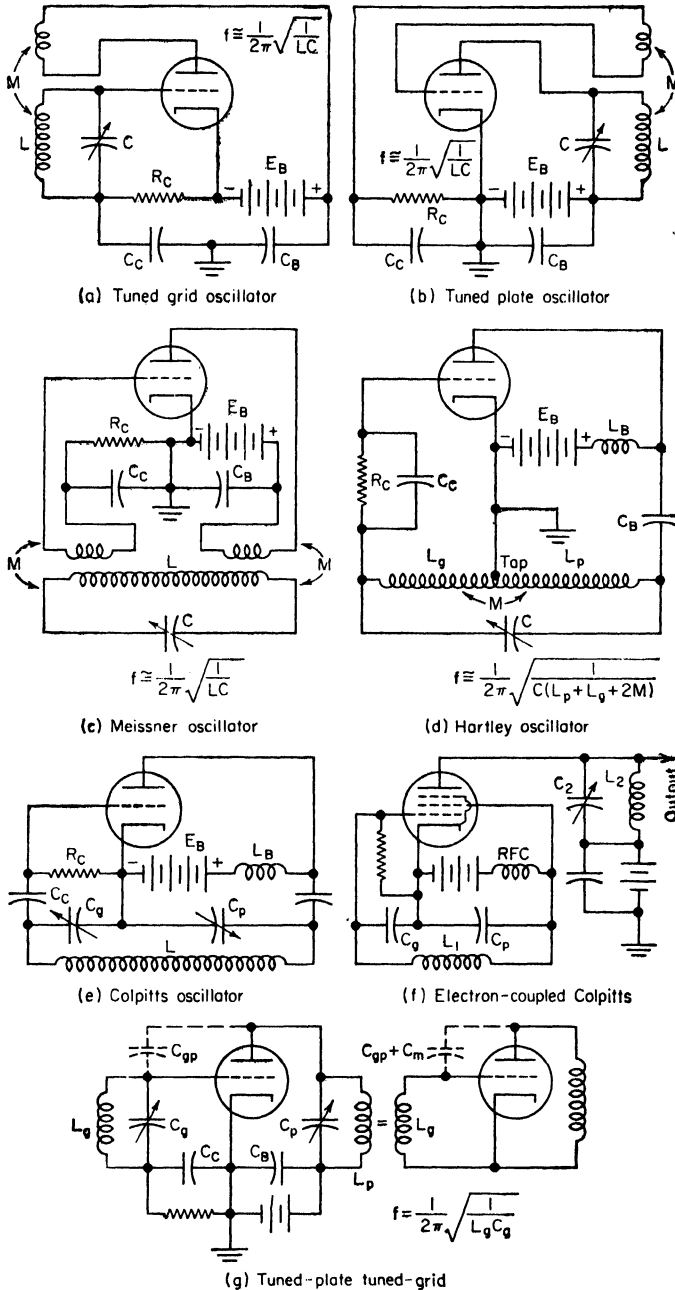
[1] Gouriet, G. G., High-stability Oscillator, *Wireless Engr.*, April, 1950, pp. 105–112.


FIG. 22. Types of feedback oscillators.

work over a wide frequency range by changing or switching coils, and it requires only one capacitor for tuning.

The tuned-plate oscillator is often used in test equipment where wide frequency ranges are to be covered with relatively low power output.

The Meissner oscillator has been used in various applications at both high and low power. It is almost impossible to make this oscillator perform properly over anything more than a very narrow frequency range, since the many possible parasitic resonances must be suppressed if successful operation is to result. Nevertheless, this circuit has been used at very high power level, in a cyclotron, because the reduction in fed-back driving power to the grid circuit is automatic when the dee resonator arcs over, thus preventing catastrophic damage to the dees when an arc occurs. Another application of the Meissner circuit substituted a high-Q transmission-type cavity resonator for the usual lumped-circuit elements. With a good microwave triode (W. E. 416-B), a stable oscillator was constructed, using this circuit, for use with a cesium-beam apparatus. The oscillator operated near 3,064 Mc and a diode-type harmonic generator was used to obtain output near 9,192 Mc.

The Hartley oscillator is especially useful at low frequencies from the audio range up to approximately 40 to 50 Mc. At low frequencies, it is possible to maintain stable feedback conditions because of the tapped inductance even though circuit Q and impedance may vary widely with tuning. This circuit is used, for example, in several widely used grid-dip oscillators where freedom from variation in feedback is essential, and also in a general-purpose test oscillator covering the range from 5 kc to 50 Mc. It is also used in many transmitters in the low- and medium-frequency bands, where crystal frequency control is not essential, usually followed by an amplifier.

The Colpitts oscillator is widely used because of its relatively good stability and low-harmonic output. It is used almost exclusively at frequencies above 100 Mc where almost any tunable oscillator tends to become a Colpitts circuit with the tube capacitances as the limiting values of C_g and C_p.

The tuned-plate tuned-grid oscillator is sometimes used to provide different impedance levels in the plate and grid circuits where, for example, high-voltage tuning capacitors may be available for only part of the circuit. It is then possible to use the *TP-TG* circuit with a large low-voltage-rating capacitor to tune the grid circuit of an oscillator to supply reasonable amounts of power with fairly good stability as, for example, in dielectric heating applications. Push-pull oscillators using resonant parallel lines as tuning elements for plate and grid circuits with cathode grounded are examples of the tuned-plate tuned-grid oscillator circuit.

The grounded-grid oscillator is similar in operation to the *TP-TG* oscillator. It is used principally in the u-h-f band since (1) disk-seal tubes are available which are well suited for use in this circuit, and (2) almost no other circuit is as satisfactory in this range. Coaxial-line resonators are usually employed with disk-seal tubes, wide tuning ranges being afforded by the adjustment of the coaxial line length with sliding plungers.

HIGH-FREQUENCY OSCILLATORS

At frequencies above about 100 Mc, the performance of conventional oscillators is significantly affected by the following factors:

1. Transit time
2. Lead and electrode inductance and capacitance
3. Circuit losses

The maximum frequency at which oscillations can be obtained with a particular tube and circuit is usually limited by one or more of the above factors.

21. Transit Time. At high frequencies, the time required for an electron to travel between various tube electrodes, which is referred to as transit time, cannot be

assumed to be negligible. The velocity v of an electron is proportional to the square root of the potential V through which it has traveled.

$$v = 5.93 \times 10^7 \sqrt{V} \quad \text{cm per sec}$$

Since electrons start at approximately zero velocity at the cathode and since the cathode-grid voltage is usually small, the transit time between the cathode and grid in conventional tubes is relatively large. The transit time between grid and plate, however, is usually much smaller than the cathode-grid transit time even though the distance is greater because electrons enter the space with an appreciable velocity and because the plate potential is much higher than that of the grid.

Two effects of transit time are of prime importance: (1) the reduction of and phase shift in the effective transadmittance (at low frequencies equal to the transconductance) of the tube and (2) the increase in grid loading. The variation in the magnitude and phase of the transadmittance as a function of transit angle[1] is shown in Fig. 23. The transit angle is the ratio of the electron-transit time to the period of the signal expressed as an angle. Since the cathode-grid transit time is usually the largest, it will have a significant effect at a much lower frequency than will the grid-plate transit time. Note that the effective transadmittance initially decreases from the d-c value as the frequency is increased and that its phase angle becomes increasingly lagging.

FIG. 23. Magnitude and phase of the effective transadmittance as a function of transit angles. (*From Llewellyn and Peterson.*)

At low frequencies, the current induced in the grid circuit by the electron stream leads the grid voltage by 90 deg and hence effectively increases the grid-to-cathode capacitance. At high frequencies, transit time causes the phase angle of the induced current with respect to the grid voltage to be less than 90 deg and hence results in a conductive component in the input admittance.[2] The input conductance increases approximately as f^2, and therefore the parallel input resistance decreases as f^2, as shown[3] in Fig. 24. As a result, the grid losses increase at the higher frequencies and

[3] Lavoo, N. T., *Proc. IRE*, **35**, 1248, November, 1947.

can be a serious limitation on the maximum frequency at which oscillations can be obtained.

22. Lead-reactance Effects. Lead inductances and electrode capacitances can also be important factors. Inductance in the cathode lead[1] primarily causes the grid input resistance to decrease as f^2 in the same manner as does the electron-transit time.
FIG. 24. Input resistance of typical receiving tubes under normal operating conditions as a function of frequency.

The combination of internal lead inductance and electrode capacitance limits the maximum frequency at which oscillations can be obtained with lumped circuits. This limit is usually reached when the inductive reactance of the leads equals the reactance of the interelectrode capacitances effectively in series and in parallel, respectively, with the resonant circuit as shown in Fig. 25. Under these conditions, a parallel-resonant circuit will appear across the actual tube electrodes with the tube external circuit connections short-circuited. Somewhat higher oscillating frequencies can be obtained with lumped circuits by the connection of a capacitor across the tube terminals in place of the resonant or short circuit.[2]

[2] Pettit, J. M., *Proc. IRE*, **38**, 633, June, 1950.

Losses due to skin effect in the conductors, whose resistance increases as the square root of frequency, and dielectric losses in the glass envelope also can be serious at high frequencies.

23. High-frequency Triode Oscillators. Many conventional receiving-type tubes, such as the 6AK4, 6AK5, 6C4, 6J4, 6J6, and 9002, can be used in low-power tunable oscillators with lumped *LC* resonant circuits at frequencies up to about 500 Mc. Other conventional-type tubes designed for h-f use, such as the 6F4, 6AF4, and 6AJ4, will oscillate at frequencies up to about 1,000 Mc with special types of lumped resonant circuits. Special types of triode tubes, such as the 2C40, 2C39, 2C37, 5675, and 416A, are suitable for use as oscillators at frequencies up to about 4,000 Mc.

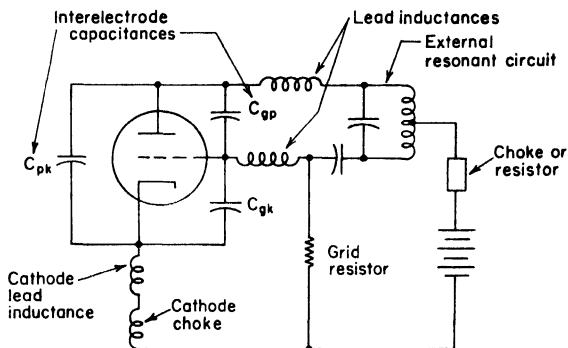
FIG. 25. Typical low-power, high-frequency triode oscillator showing interelectrode capacitances and lead inductances.

High-power tubes of conventional construction have top frequency limits in the 50- to 100-Mc frequency range while special types of high-power triodes are available for use up to about 1,000 Mc.

In most low-power oscillators for use below 1,000 Mc, the modified Colpitts circuit of Fig. 25 is used in which the feedback required for oscillation is obtained by means of the interelectrode tube capacitances.[1] In this arrangement, the cathode and heater are "floating" with respect to ground to eliminate the effect of cathode-lead inductance and external capacitances on the operation. Although it is not possible to make the impedance between cathode and ground infinite as is required for a perfect "floating" cathode, satisfactory performance over a wide band of frequencies can be obtained by the use of properly designed chokes in the heater and cathode leads.[2]

The inductance in variable capacitors used in the resonant circuit must be held at a minimum to obtain optimum high-frequency performance. Balanced, split-stator variable capacitors perform well at high frequencies since low-inductance connections can be made to the stator segments and the connection to the rotor, which usually has a relatively large inductance, is eliminated. With the balanced capacitor, the inductor usually consists of one or more straps or bars connecting the two stator sections.

LC resonant circuits with tuning ranges of the order of 5 to 1 can be obtained if the rotor of the variable capacitor is used to reduce the parallel inductance in the circuit by eddy-current shielding as the capacitance is decreased. One type of circuit which performs this function is the *butterfly* circuit.[3] A symmetrical butterfly and its equivalent circuit are shown in Fig. 26. As the rotor leaves the stator, it reduces the area through which the magnetic field set up around the inductance arm can pass and thus decreases the inductance. Figure 27 is a symmetrical butterfly oscillator which operates over the frequency range from 250 to 920 Mc.

24. Oscillators for 1,000 Mc and Above. At frequencies above 1,000 Mc, lumped-circuit resonators become impractical since they must be made very small and usually have low *Q*, and the magnitude and distribution in the circuit of the stray inductances and capacitances have a drastic effect on the performance. At these frequencies,


[1] Kamphoefner, F. J., *Proc. IRE*, **38**, 630-632, June, 1950.

[3] Karplus, E., *Proc. IRE*, **33**, 426, July, 1945. Radio Research Laboratory Staff, *op. cit.*, Secs. 28-7 to 28-16; Chap. 30.

distributed-parameter resonators, such as coaxial-line or cavity resonators, are useful since their resonant frequencies can be accurately calculated, they have high Qs, and they are reasonable in size. A length of coaxial line with movable short-circuiting plunger is a commonly used type of resonator.
FIG. 26. (*a*) Symmetrical butterfly resonator with rotor set for minimum resonant frequency. No eddy-current shielding of the inductance arms by the rotor is obtained with this setting. (*b*) Butterfly set near middle of tuning range. Appreciable reduction in inductance due to eddy-current shielding is secured. (*c*) Equivalent circuit of butterfly resonator.
FIG. 27. Butterfly oscillator for 250 to 920 Mc.

To realize the advantages of the coaxial-line resonators, the lead inductance in the connections from the oscillator tube to the coaxial-line circuit must be very small. To achieve this, high-frequency tubes are constructed with the leads made in the form of disks or cylinders which pass directly through the glass and which actually become part of the coaxial-line circuit. In the 5675 pencil triode,[1] the cathode, grid, and plate are cylindrical structures with the grid connection made by means of a

[1] Rose, G. M., D. W. Power, and W. A. Harris, *RCA Rev.*, **10**, 321, September, 1949.

flange and the cathode and plate connections made by means of cylindrical terminals, as shown in Fig. 28. The electrode spacing and hence the transit time are small and operation up to about 3,000 Mc with power outputs of about ½ watt at 1,700 Mc and 50 mw at 3,000 Mc is possible.

Fig. 28. Cross section of pencil-type tube.

Still higher-frequency tubes are constructed using the *disk-seal, planar-grid*, or *lighthouse* principle in which the cathode, grid, and plate are all parallel-plane electrodes as shown in Fig. 29. Types 2C40 and 2C43 lighthouse tubes[1] and the 2C37 *rocket* tube make satisfactory low-power oscillators at frequencies up to about 3,500 Mc. Power outputs of the order of 40 watts at 1,000 Mc and 18 watts at 2,500 Mc can be obtained with inverted lighthouse tubes, such as the type 2C39. In this type of tube, the plate is at the large end of the tube and hence can be readily cooled.

Fig. 29. Cross section of type 2C40 lighthouse tube.

Still higher-power disk-seal tubes are available for use up to about 1,200 Mc. Tubes such as the 5588 and 4CX250K are capable of generating of the order of 100 watts of c-w power at 1,000 Mc with about 30 per cent efficiency. Other tubes, which are usually used as power amplifiers, such as the 6448, produce c-w outputs of up to 11 kw at frequencies up to 900 Mc.

The extreme in close-spaced, microwave triode tubes[2] is the 416-A shown in Fig. 30. This tube has a cathode-grid spacing of 0.0006 in., a grid-wire diameter of 0.0003 in., a grid-plate spacing of 0.012 in., and a transconductance of 50,000 μmhos. The tube will function as an oscillator considerably above 4,000 Mc.

25. Line Oscillators. Coaxial-line oscillators can be constructed which use only a single resonator[3] in a circuit similar to that shown for lumped-circuit oscillators in Fig. 25. In this arrangement, the tube is connected across one end of the coaxial line, with the grid connected to the outer conductor and the plate to the inner, and a short circuit is placed at the other end of the line. With most high-frequency tubes, the plate-cathode capacitance is usually too small to produce the amount of coupling
[1] McArthur, E. D., *Electronics*, **18**, 98, February, 1945. Reich, H. J., P. F. Ordung, H. C. Krauss, and J. C. Skalnik, "Microwave Theory and Techniques," Chap. 11, Van Nostrand, 1953.

[3] Radio Research Laboratory Staff, *op. cit.*, Chap. 32.

required for oscillation, and additional external coupling must be provided. If a wide tuning range is desired, it may be difficult to design a coupling element which performs satisfactorily over the whole frequency range. Also the top frequency is usually limited to the natural resonant frequency of the tube, which is that obtained with the short circuit as close as possible to the tube with the coaxial line operating in its quarter-wave mode. Usually the frequency limit is around 1,800 Mc.

FIG. 30. Bell System type 416-A "closed-spaced" triode.

For operation at higher frequencies and for more efficient operation at lower frequencies, two resonant lines are used. One is connected between grid and plate and the other between grid and cathode[1] as shown in Fig. 31. The grid-cathode line can be folded back on the grid-plate line to save space, as shown in Fig. 32. With two resonators, the proper feedback conditions can be produced to force the circuit to oscillate with the cavities in the $\frac{3}{4}\lambda$ mode rather than the $\lambda/4$ mode. Under these conditions, the frequency range is not limited by the natural resonant frequency of the tube and much-higher-frequency operation can be obtained. As in the single-cavity oscillator, the plate-cathode capacitance is usually too small to provide the proper coupling; therefore a small amount of additional coupling must be provided between the cavities. Small loops or probes are satisfactory for this purpose.

With movable short circuits, wide frequency ranges can be obtained with coaxial-line oscillators using disk-seal tubes. A range from 300 to 3,000 Mc is realizable with the proper circuit design.[2] The short-circuiting elements in the coaxial line can be of the finger type, in which actual physical contact is made between the plunger and the line, or they can be of the noncontacting or choke type,[3] in which no actual connections are made but a very low r-f impedance is produced at the face of the plunger. Figure 33 shows several types of noncontacting plungers along with their performance characteristics. Note the excellent broad-band characteristics of the S-type plunger.

FIG. 33. Rear-cavity power loss of basic noncontacting plungers. The ratio of characteristic impedance of main coaxial line to that of the gaps on either side of the plungers m is assumed to be 18.6 in the graph.

High-power triode oscillators can be obtained by the use of a number of disk-seal tubes mounted in an annular resonator.[1]

The *Resnatron*[2] is a very-high-power tetrode oscillator in which the tube electrodes are actually an integral part of the coaxial-line resonators, as shown in Fig. 34. Power outputs of the order of 60 kw c-w have been obtained over the 340- to 625-Mc frequency band.

[1] Priest, D. H., *Proc. IRE*, **38**, 515, May, 1950.
[2] Radio Research Laboratory Staff, *op. cit.*, Chap. 19.

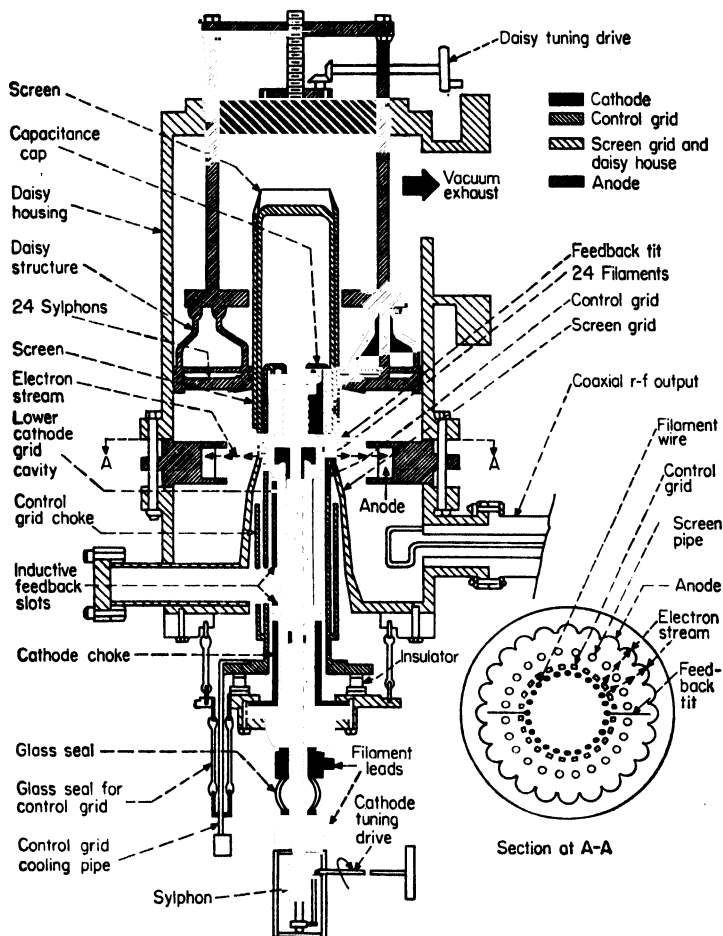
26. Barkhausen-Kurtz Oscillators. The extension of the frequency range of oscillators using conventional l-f circuits by the production of tubes with decreased electrode spacing seems to have reached a practical limit and oscillators based on entirely different principles have been responsible for major extensions of the frequency range into the millimeter wavelengths.


FIG. 34. Basic structure of Resnatron.

An early oscillator which made use of the transit-time effect for its operation was the Barkhausen-Kurtz oscillator,[1] which was developed in 1920. As shown in Fig. 35, this oscillator uses a fairly conventional triode operated with the plate at low negative potential and the grid at high positive potential. Electrons attracted from the

cathode region by the positive grid penetrate the retarding field between the grid and plate and are stopped and returned to the grid. On the return trip, most of the electrons do not strike the grid but pass through into the grid-cathode region and then are reflected back again. Electron clouds therefore oscillate around the grid at a frequency primarily determined by the grid potential. Electrons which give up energy to the grid oscillate about the grid many more times than those which receive energy from the grid before striking it and, therefore, r-f oscillations can be maintained. A negative resistance consequently appears between the grid and plate, and if a resonator of sufficiently high impedance is connected across these electrodes, the circuit will oscillate. In general, the efficiency obtained with this type of oscillator is low and it has been replaced by two types of oscillators.
Fig. 35. Barkhausen-Kurtz oscillator employing resonant lines.

27. Klystron Oscillators. Klystrons[1] are h-f oscillators which depend upon transit time and velocity modulation of an electron beam for their operation and hence will oscillate at frequencies far above the maximum limit of triode oscillators. The word klystron is derived from the Greek "klyzein" which refers to the breaking of waves on a beach.

A klystron consists of a cathode, two cavity resonators, and a collector arranged as shown in Fig. 36. A cavity resonator[2] is a high-frequency resonant circuit in which the r-f electric and magnetic fields are completely contained within the resonator. Electrons are emitted from the cathode and travel toward the *buncher* gap under the influence of a high d-c voltage. The electrons pass through the buncher gap at a high velocity and then enter the field-free drift space in which their velocities remain constant. At the end of the drift space, the electron beam passes through the *catcher* gap and then strikes the collector. The grids on either side of the buncher and catcher gaps are connected to the cavity resonators tuned to the oscillating frequency. Therefore, if the buncher resonator is excited, an r-f voltage appears between the grids on either side of the buncher gap, which *velocity-modulates* the electron beam. This means that electrons which pass through the gap when the r-f electric field between the two grids is negative or retarding will be slowed down and electrons which pass through the gap when the r-f field is positive or accelerating are speeded up. Therefore, in the drift space, the accelerated electrons tend to catch up with the retarded electrons and form bunches as shown in the *Applegate diagram* in Fig. 37. As can be seen, the beam current passing through the catcher gap under these conditions is not uniform with respect to the time but is amplitude-modulated at the r-f frequency. The r-f component of the beam current passing through the catcher gap induces an r-f voltage across the catcher resonator and thus delivers r-f power to it. If some of the r-f energy from the catcher resonator is coupled back into the buncher resonator by means of a coupling loop or transmission line and the phasing is adjusted properly, oscillations will be maintained.

A fixed feedback circuit can be used and the phase adjusted for the desired oscillating conditions by means of the d-c voltage appearing between the cathode and buncher. This voltage controls the electron velocity and hence the time spent in the drift space which determines the phase of the electronic coupling between the buncher and catcher resonators. As shown in Fig. 38, oscillations will occur at several values of d-c voltage. Between the center of each mode, the electron drift time changes by the period of one r-f cycle. Oscillations will occur over a considerable range of voltage in each mode because the deviation in phase shift in the beam coupling from the desired value caused by the change in d-c

Fig. 36. Two-cavity klystron.
Fig. 37. Applegate diagram of two-cavity klystron.

voltage is compensated by a change in phase shift in the cavity resonators. The change in phase shift in the cavity resonators is produced by a small change in the frequency of oscillation. As a result, the oscillator can be frequency-modulated over ranges of the order of several megacycles by the application of a modulating voltage to the d-c beam voltage.

FIG. 38. Typical output power and frequency characteristics of type 410R two-cavity 3,000-Mc klystron oscillator.

Figure 39 shows a cross-sectional view of a typical two-cavity klystron. The resonators can be tuned over a relatively narrow frequency range by a variation in the spacing between the grids in each resonator which causes a change in the capacitance loading. One end of each resonator contains a flexible diaphragm which will allow axial movement of one of the grids without the use of complicated movable vacuumtight joints.

Klystrons have been developed which can be tuned over wide frequency ranges. In these tubes, the resonators are external to the vacuum and connections between the resonators and the grids at the buncher and catcher gaps are made by means of disks which pass through the vacuum seal.

Klystron oscillators are capable of producing large amounts of c-w or pulsed r-f power at microwave frequencies. However, for most high-power applications, three or more resonator klystron amplifiers are used rather than klystron oscillators because of the better frequency stability and higher efficiency obtained. Commercial klystron amplifiers are available which are capable of producing c-w power outputs of about 10 kw at frequencies up to 2,400 Mc and pulsed power outputs of 4 megawatts in the 3,000-Mc range. Efficiencies of from 30 to 45 per cent are obtained. Other experimental tubes, designed for pulsed operation, produce peak outputs of 30 megawatts at 3,000 Mc and still others generate power around the 150-watt level at frequencies up to 40 kMc.

FIG. 39. Structure of two-cavity klystron. (*Sperry Gyroscope.*)

28. Reflex-klystron Oscillators. A widely used type of microwave oscillator is the reflex-klystron oscillator.[1] This type of klystron requires only a single resonator,

[1] Pierce, J. R., *Proc. IRE*, **33**, 112, February, 1945. Hamilton, Knipp, and Kuper, *op. cit.* Ginzton, E. L., and A. E. Harrison, *Proc. IRE*, **34**, 97, 1946. McNally, J. O., and W. G. Shephard, *Proc. IRE*, **35**, 1424, 1947. Reich, Ordung, Krauss, and Skalnik, *op. cit.*, Chap. 13. Spangenberg, K. R., "Vacuum Tubes," McGraw-Hill, 1948.

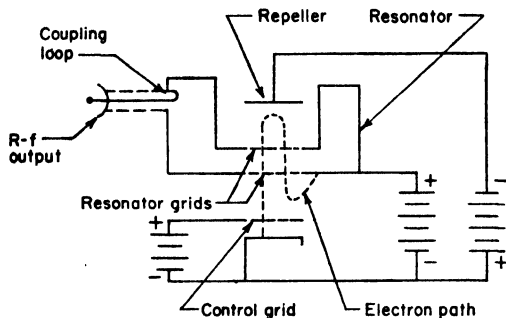
as shown in Fig. 40, and hence is simpler in construction and operation than a multi-cavity klystron. The primary uses of this oscillator are in applications in which only small amounts of power are required, as for local oscillators in receivers, oscillators for signal generators, and low-power point-to-point microwave transmitters.


Fig. 40. Reflex klystron.

In a reflex klystron, the electron beam is accelerated by a d-c potential between the cathode and first grid of the resonator as in the two-cavity klystron. However, on leaving the resonator gap, the beam passes into a d-c retarding field space produced by a repeller electrode which is at a potential below that of the cathode. An electron will penetrate this space a distance which depends upon the velocity it has when entering the space. After being brought to rest by the retarding field, it will be accelerated in the opposite direction, thus passing back through the grids of the resonator. The same type of bunching action occurs in the reflex klystron as in the two-cavity tube. However, only one resonator is required and no external feedback connection is necessary. The proper phasing for oscillation is obtained by adjustment of the d-c repeller voltage. Figure 41 is a plot of the paths of various electrons in the retarding field area as a function of time under typical con-
Fig. 41. Typical paths of electrons passing through the resonator at various times during an r-f cycle in a reflex klystron.

ditions and indicates how the bunches are formed. The variation in power output with repeller voltage is shown in Fig. 42; the several modes which can exist are indicated. As in the two-cavity klystron, the centers of the modes correspond to the transit angles of $(\frac{3}{4} + n)$ r-f cycles, where n is an integer called the *mode number*. The frequency of oscillations varies slightly over each mode as indicated. Consequently, the oscillator can be used to produce f-m signals or for automatic frequency control by the application of the modulating voltage to the repeller electrode. The highest-power mode of oscillation is the one in which the electrons require a time interval corresponding to three-quarters of an r-f cycle to make the round trip through the retarding-field space. However, this mode requires a very high resonator impedance for oscillation, and hence it is not often found. The power output and resonator impedance required generally drop as the mode number increases.

Reflex klystrons are commercially available with built-in resonators for frequencies between about 1,200 Mc and above 60 kMc with power outputs from a few milliwatts to several watts. Experimental tubes have been built which operate at considerably higher frequencies.[1] Tuning ranges of the order of 10 per cent are obtained. Figure 43 is a cross-section drawing of a typical narrow-band reflex klystron.

Wide tuning ranges can be obtained with reflex-klystron tubes designed for use with external resonators.[2] These tubes have the resonator grid connections brought out through the vacuum on copper disks as shown in Fig. 44. The external resonator can be a length of coaxial transmission line with a movable short circuit, as shown in Fig. 45, or a short-circuited wave guide.[3] The short circuit can be of the sliding-contact type or of the choke or noncontacting type (see Sec. 25). Tuning ranges as great as 5 to 1 have been obtained with the coaxial circuits at frequencies in the 1- to 10-kMc range and tuning ranges of the order of 2 to 1 are obtainable at even higher frequencies.
FIG. 42. Power output and frequency variation with repeller voltage for type 5976 reflex-klystron oscillator.
FIG. 43. Western Electric type 2K29 reflex klystron, 3,400 to 3,900 Mc.

If a single tuning control is desired, the repeller voltage must be tracked with the cavity tuning. The repeller voltage-frequency characteristic is practically linear;

however, the plunger position in the cavity is approximately proportional to wavelength rather than to frequency. Many methods,[1] such as the use of nonlinear gears, a tapped voltage-divider system, a tapered voltage-divider system, or a variable-transformer system, are satisfactory for tracking purposes.

29. Magnetron Oscillators. An important type of h-f oscillator is the magnetron.[2] Magnetrons have been very widely used for the generation of pulsed r-f power in radar systems at microwave frequencies. Efficiencies up to 80 per cent and peak power outputs as high as 10 megawatts have been obtained in the microwave frequency band. Recently, a new type of magnetron has been developed which can be tuned by variations in voltage alone over frequency ranges as large as 4 to 1.

In a magnetron, electrons move under the influence of crossed electric and magnetic fields. In general, a magnetron consists of a cylindrical cathode surrounded by a cylindrical anode. A d-c voltage is applied between the cathode and anode, and a magnetic field is applied parallel to the axis of the cylindrical electrodes. An electron which leaves the cathode under the influence of the d-c voltage is deflected from a radial path between the cathode and anode by the force produced by the magnetic field[3] as shown in Fig. 46. This
Fig. 46. Typical electron paths in cylindrical magnetron. The potential between cathode and anode is the same in all cases, but the magnetic field increases from (*a*) to (*b*).

force is proportional to the strength of the magnetic field and to the velocity of the electron. Its direction is at right angles to both the magnetic field and the direction of motion of the electron. Therefore, with proper settings of the magnetic field and the d-c voltage, electrons emitted from the cathode can be made to travel directly from the cathode to the anode, to spiral around the cathode before striking the anode, or to loop around and return to the cathode, in which case the anode current is cut off. The voltage which marks the transition between a finite anode current and zero anode current with a fixed value of magnetic field is called the *cutoff voltage*. Theoretically under the proper conditions, electrons can be made to circle about the cathode indefinitely and never return to either the anode or cathode. However, it is not believed that this condition is obtained in practice. Most magnetrons are designed to be in the cutoff region when the r-f field is absent.

There are three basic types of magnetrons. The *negative-resistance magnetron* depends for its operation upon a static negative resistance produced under certain conditions in a magnetron. This type of operation is affected by transit time and hence is usually useful only at the lower frequencies. The *cyclotron-frequency magnetron* depends for its operation upon the periodic radial component of motion of the electrons parallel to and in synchronism with a radial r-f electric field. In the *traveling-wave magnetron*, the r-f field is primarily a tangential field and produces bunching of the electrons around the interaction space like spokes on a wheel. This space-charge cloud rotates in synchronism with the rotating traveling r-f field which is set

up in interaction space between the anode and cathode in the magnetron. Most high-power modern magnetrons are of the latter type.

30. Negative-resistance Magnetron Oscillators. Negative-resistance magnetron oscillators are usually of the split-anode type shown in Fig. 47 in which the cylindrical anode is split into two equal segments. The frequency of oscillation is determined by the resonant frequency of the tuned circuit connected between the two anode segments and the operation is not critically dependent on the magnetic field.

FIG. 47. Split-anode magnetron.
In this oscillator, the d-c voltage between the anodes and the cathode is well below the cutoff voltage. When, in addition, an a-c voltage is applied across the anode segments, the potentials of the two anode segments are periodically raised and lowered in opposite phases. Under these conditions, electrons tend to spiral out from the cathode and strike the anode segment at the lowest potential, as shown in Fig. 48, thus producing a negative a-c resistance.[1] Negative-resistance magnetrons are limited to relatively low-frequency operation since the transit time of electrons between the cathode and anode must be a small fraction of an r-f cycle. The upper frequency limit is of the order of 1,500 Mc, and in this range, very large magnetic fields are required.
FIG. 48. Typical electron paths in negative-resistance split-anode magnetron.

31. Cyclotron-frequency Magnetron Oscillators. An electron which leaves the cathode under the influence of the anode voltage will start toward the anode. However, as it gains velocity, it will be deflected by the right-angle force produced by the magnetic field which is proportional to the velocity of the electron and to the strength of the magnetic field. If the anode voltage is below the cutoff value, the electron will loop around and return to the cathode. The frequency corresponding to the time required for an electron to complete one loop or cycle in a parallel-plane magnetron is called the cyclotron frequency f_c. The cyclotron frequency in a parallel-plane magnetron is determined only by the strength of the magnetic field:

$$f_c = 2.8 \times 10^6 B$$

where f_c is the frequency in cycles and B is the magnetic field strength in gausses. In a cylindrical magnetron, the operation is similar, as shown in Fig. 46, but the frequency of the radial component of the electron motion is lower than the cyclotron frequency.

If an r-f voltage having a frequency equal to that of the radial component of the electron motion is applied between the cathode and anode, electrons which leave the cathode in such a phase as to gain energy from the r-f field as they travel toward the anode will also gain

[1] Kilgore, G. R., *Proc. IRE*, **24**, 1140, 1936.

energy from the r-f field on their return to the cathode. These electrons will therefore strike the cathode with more energy than they had when they left and hence will be removed from further interaction with the r-f field. However, electrons which leave the cathode in such a phase as to give up energy to the r-f field as they move toward the anode will also lose energy on their return to the cathode. These electrons will not have sufficient energy to reach the cathode and will therefore start back toward the anode on another loop and give up still more of their energy to the r-f field. These electrons will continue to give up energy to the r-f field until the amplitude of their radial oscillation becomes zero. At this time, they must be removed or they will start to absorb r-f energy. In general, electrons emitted from the cathode which tend to absorb r-f power are rapidly eliminated and electrons which deliver power to the r-f field are allowed to multiply. As a result, if a resonant circuit is connected between the cathode and anode and tuned to the frequency of the radial oscillation of the electrons, r-f power will be generated.

Cyclotron-frequency magnetrons can also be of the split-anode type, but neither type is very widely used because the frequency is critically dependent on the magnetic field and both the power output and efficiency are low. Power outputs of 100 watts can be obtained at a frequency of 600 Mc and 1 watt at 3,000 Mc. Efficiencies lie between 1 and 10 per cent.
FIG. 49. Cross sections of several types of multicavity magnetrons.

32. Traveling-wave Magnetron Oscillators. Traveling-wave magnetron oscillators are the most widely used type of magnetron because of their high efficiency, high power output, and adaptation to use over frequency ranges of from a few hundred megacycles to the millimeter range. The operation of this type of magnetron depends upon the interaction of a rotating r-f field with a synchronously rotating space-charge cloud in a manner analogous to an a-c generator.

The traveling r-f wave can be set up by a number of different types of structures, and magnetrons are usually classified by the structure used. These classifications are:

1. Multicavity magnetrons
2. Split-anode magnetrons
3. Interdigital magnetrons

Multicavity magnetrons are built in several forms, some of which are: (1) hole-and-slot magnetron, (2) slot magnetron, (3) vane magnetron, and (4) rising-sun magnetron. Cross-sectional views are shown in Fig. 49. In all these magnetrons, a number of

cavities are located around the circumference of the anode. The cavities are parallel-resonant circuits which are all connected in series in a ring as shown in the equivalent circuit in Fig. 50. If this circuit is excited by r-f energy at the proper frequency, a
Fig. 50. Approximate equivalent of a hole-and-slot magnetron.
Fig. 51. Electric field distribution in a hole-and-slot magnetron operating in the π mode.

standing wave will be set up around its circumference. A standing wave is equivalent to two waves of equal amplitude traveling in opposite directions. The wave traveling in the same direction and at the same speed as the rotating space charge interacts with it, while the wave traveling in the opposite direction has little effect. Standing waves can be set up at a number of frequencies corresponding to different modes of operation, a characteristic which can be very troublesome. Usually magnetrons are designed to operate in the π mode, in which adjacent cavities are 180 deg out of phase with one another as indicated in Fig. 51. Low-frequency magnetrons are usually "strapped" to force them to operate in the π mode. Strapping consists in connecting together alternate anode segments, which are in the same phase in the π mode, by means of copper straps, as shown in Fig. 52.

Fig. 52. Structure of a strapped magnetron. (*From Slater.*)

In a traveling-wave magnetron, electrons under the influence of the axial magnetic field and radial electric field follow approximately epicycloidal paths which progress around the cathode. The average velocity of the progression depends on the relative strengths of the d-c electric and magnetic fields. If the fields are chosen properly, the average rotational velocity can be made equal to that of the traveling r-f wave propagated along the anode. In a magnetron operating in the π mode, the r-f electric field is as indicated in Fig. 51. An electron which encounters .an accelerating tangential component of the r-f electric field absorbs energy from the field and has its velocity increased and thus tends to return to the cathode. An electron which encounters a retarding tangential component of the r-f field delivers energy to the field and tends to have its velocity reduced. The lower velocity

causes this electron to move closer to the anode, and in doing so, it obtains more energy from the d-c electric field and therefore tends to regain its original rotational velocity. These electrons therefore remain in synchronism with the rotating r-f electric field and continue to abstract energy from the d-c field and deliver energy to the r-f field until they strike the anode. Figure 53 shows typical paths of electrons and indicates the space-charge bunches which rotate about the interaction space like spokes on a wheel. The radial
FIG. 53. Space-charge distribution and electron paths in magnetron. The paths indicated are relative to the space-charge cloud which is rotating in synchronism with the traveling r-f wave.

component of the r-f field also helps to maintain the electrons in the space-charge bunches in the proper phase by a process known as *phase focusing*.

Split-anode magnetrons operating in the traveling-wave mode are similar to multicavity magnetrons in operation, with the difference that the rotational velocity of the traveling r-f wave is much larger since there are only two anode segments. This requirement tends to limit the maximum frequency of oscillation with practical values of d-c voltage and magnetic field.

Interdigital magnetrons are traveling-wave magnetrons utilizing a single resonator in which the anode segments are fingers extending from both ends of the resonator, as shown in Figs. 54 and 55. Adjacent fingers are connected to opposite ends of the resonator and hence are 180 deg out of phase. A rotating traveling wave is set up in the same manner as in multicavity magnetrons. Since only a single resonant circuit is required, these magnetrons can be easily adapted to being tuned over wide frequency ranges.

The performance of magnetron oscillators is greatly affected by the load impedance appearing at the coupling loop. The actual power output and frequency of oscillation

for various load impedances can be determined from a Rieke diagram, shown in Fig. 56. In this diagram, contours of constant power and contours of constant frequency are plotted on a Smith chart in which constant-VSWR or reflection-coefficient contours are circles about the center of the chart and contours of constant distance along the
Fig. 54. Typical traveling-wave magnetron with magnet. (*From Sylvania.*)
Fig. 55. Interdigital magnetron construction.

line from a reference point, usually the output terminals, to a voltage minimum on the output line or wave guide are radial lines.

33. Tunable Magnetron Oscillators. As pointed out above, interdigital and split-anode magnetrons can be tuned over wide frequency ranges by adjustments

of the resonator tuning. Multicavity magnetrons are more difficult to tune but tuning over about 10 per cent ranges can be obtained by the insertion of rods in the cylindrical cavities or plates in the slots of hole-and-slot magnetrons. The rod method is mainly inductive tuning while the plate method is mainly capacitive tuning.
FIG. 56. Typical Rieke diagram.
FIG. 57. Type Z5112 voltage-tunable magnetron. (*From General Electric.*)

34. Voltage-tunable Magnetron Oscillators. Interdigital magnetrons can be constructed which can be tuned by variations in voltage alone over frequency ranges as great as 4 to 1. An outline view of one version of this type of tube[1] is shown in Fig. 57.

[1] Welch, H. W., Jr., *Proc. IRE*, **41**, 1631, November, 1953. Boyd, J. A., *Proc. IRE*, **43**, 332, March, 1955. Wilbur, D. A., and P. H. Peters, *Proc. Nat. Elec. Conf.*, **11**, 368, 1955.

As previously pointed out, in a traveling-wave magnetron the traveling wave must stay in synchronism with the rotating space charge if oscillations are to be produced. Therefore, the velocity of the traveling wave and hence the frequency of oscillation are proportional to the rotational velocity of the space-charge wave. Since the velocity of the space-charge wave is proportional to the applied d-c voltage, the oscillating frequency also will be a linear function of the applied voltage.

Most magnetrons cannot be voltage-tuned over wide frequency ranges because the Qs of the associated anode resonators are too high, and if the Qs are lowered by loading, the oscillations cease before the tuning range can be greatly increased. It has been found, however, that if the cathode current is maintained constant, the oscillator will function with load impedances of only a few ohms at a frequency primarily determined by the applied d-c voltage. Under these conditions, the magnetron
FIG. 58. Tapered wave-guide cavity for voltage-tunable magnetron.
FIG. 59. Ridge wave-guide cavity for voltage-tunable magnetron.

appears to be a constant-current generator whose output terminals are shunted by the capacitance between the vanes of the interdigital structure. The power output is therefore approximately proportional to the load resistance. Since the load is shunted by the fixed vane capacitance, the band width of the output circuit and the tuning range are inversely proportional to the load resistance and the power output. Tuning ranges of over 4 to 1 have been obtained with a power output of about ¼ watt. For a 2:1 band width, a power output of about 1 watt is obtainable, and over band widths of a few hundred megacycles, an output of 10 watts can be obtained.

Since the required load impedance for broad-band operation is in the vicinity of 10 to 20 ohms, broad-band matching transformers are necessary to match the tube to a 50-ohm load or to a standard wave guide. Figure 58 shows a tapered wave-guide form of matching transformer used in the 2.5- to 4.0-kMc range, and Fig. 59 shows a ridge wave-guide cavity for the 3.5- to 4.7-kMc range. The power output as a function of frequency of the tapered wave-guide oscillator is shown in Fig. 60.

One problem in these tubes is that of maintaining constant cathode current. This can be accomplished by operating the cathode temperature-limited. However, back heating of the cathode by the electrons which are returned to the cathode, after having gained energy from the r-f field, makes it necessary to control the heater power supplied to maintain a constant cathode temperature. A method of overcoming this difficulty has been found. The technique is to locate the actual emitting cathode outside of the actual interaction space and to deflect the electrons into the interaction space by means of a control electrode, as shown in Fig. 57.

The plate voltage required to operate the tube is of the order of 500 to 1,500 volts and the magnetic field about 2,500 gausses. The voltage sensitivity is about 3 Mc per volt. For best operation, the tube should have a regulated d-c heater supply. The noise level in the tube has been found to be slightly higher than that of klystrons and triodes.

At present (1958), tubes are commercially available to cover the frequency range 1,000 to 4,000 Mc (Z5111, 1,000 to 2,000 Mc, and Z5112, 2,000 to 4,000 Mc) and other models are planned to extend this range in both directions. This type of oscillator is very useful for microwave sweep generators, spectrum analyzers, wide-range receivers, and various other low-power applications.

FIG. 60. Performance of type Z5112 voltage-tunable magnetron.

35. Backward-wave Oscillators.[1] Another new type of microwave oscillator is the backward-wave oscillator, some versions of which are called *Carcinotrons*. This oscillator has the important characteristic of having its frequency of oscillation controllable over ranges greater than 2 to 1 by voltage variation alone. This device is similar to a traveling-wave-tube amplifier (see Chap. 8) but differs in that the electron beam travels in the opposite direction from the wave in the slow-wave structure and as a result produces the feedback required for oscillation.

In a backward-wave oscillator, the electromagnetic wave is propagated in a slow-wave structure in which the effective velocity of the wave interacting with the electron beam has its phase velocity and group velocity in opposite directions. In Fig. 61, the slow-wave structure consists of a folded wave guide which intersects the beam periodically. If an electromagnetic wave is applied to the wave guide from the right-hand end, it will travel toward the left-hand end and interact with the beam at the points at which the guide intersects the beam. If the frequency of the wave and the electron velocity are adjusted so that an electron which encounters a peak retarding field when it passes through the extreme left-hand interaction gap also encounters a peak retarding field when it passes the next gap and all subsequent gaps, the beam will be bunched as it travels along the line and will deliver power to the wave in the same manner as in the traveling-wave tube. Note that, although the electromagnetic wave in the guide is traveling to the left, it appears to the electron beam that it is traveling to the right in synchronism with the beam. The beam delivers power to the r-f wave as it travels to the right and hence actually generates the electromagnetic wave in the guide which causes the bunching. The feedback loop con-
[1] Kompfner, R., and N. Williams, *Proc. IRE*, **41**, 1602, November, 1953. Heffner, H., *Proc. IRE*, **42**, 936, June, 1954. Johnson, H. R., *Proc. IRE*, **43**, 684, June, 1955. Warnecke, R. R., P. Guenard, O. Doehler, and B. Epstein, *Proc. IRE*, **43**, 413, April, 1955. Palluel, P., and A. K. Goldberger, *Proc. IRE*, **44**, 333, March, 1956.

sisting of the electromagnetic wave and electron beam produces self-sustaining oscillations if the beam current is sufficiently large, and r-f power output can be obtained from the left end of the wave guide. The right end of the guide is usually terminated to prevent reflections from interfering with the action.
FIG. 61. A basic type of backward-wave oscillator. (*After Pierce.*)

Since the electron beam actually generates the wave in the wave guide, the frequency of the wave will automatically adjust itself to that providing an effective phase velocity which produces the optimum oscillating conditions. As a result, the operating frequency can be varied over wide ranges by variations in the beam velocity produced by changes in the d-c beam voltage.

In practice, the interaction structure may be a helix, folded line, interdigital structure, or any other periodic structure and some types of smooth structures.

36. O-type Backward-wave Oscillator. There are two basic types of backward-wave oscillators, the O-type and M-type. The O-type oscillator is similar to a conventional traveling-wave tube in that the electrons are accelerated by a d-c electric field before entering the interaction structure only, with no d-c electric fields present in the interaction space, and the r-f energy is obtained from the kinetic energy of the electron motion.

Figure 62 is a diagram of an O-type backward-wave oscillator. A magnetic field is used for focusing purposes only and is oriented parallel to the beam. The efficiency of the
FIG. 62. Structure of O-type backward-wave oscillator with a helical slow-wave structure.

O-type oscillators is usually low, in the vicinity of 1 to 5 per cent, since the electron beam is slowed down as it gives up energy and can reach a velocity at which it absorbs energy from the r-f circuit. This type of oscillator has a voltage-frequency characteristic which is roughly proportional to f^3. The noise produced is comparable with that produced by a klystron. O-type backward-wave oscillators have been built which are voltage-tunable over about an octave in frequency with center frequencies from a few hundred megacycles up to frequencies in the millimeter range. Power outputs range from several watts at the lower frequencies to a few milliwatts at millimeter wavelengths. In general, this type of tube is suited to local oscillator and instrument applications.

37. M-type Oscillator. In the M-type backward-wave oscillator,[1] the beam is acted on by crossed electric and magnetic fields in the interaction area, as shown in

[1] Palluel and Goldberger, *loc. cit.*

Fig. 63, and the r-f energy is obtained from the potential energy of the electrons rather than from the kinetic energy. This type of oscillator is similar in principle to a magnetron.
FIG. 63. Structure of M-type backward-wave oscillator.

The electron beam is introduced at right angles to the axis of the periodic structure and under the influence of the magnetic field initially follows a curved path. At a point at which the direction of motion of the beam is parallel to the axis of the periodic structure, it is injected into the interaction region, where it also is acted on by the d-c electric field existing between the periodic structure and the sole. Under the influence of crossed electric and magnetic fields, the beam will follow a path parallel to the axis of the periodic structure. The reaction with the periodic structure is similar to that in the O-type oscillator. However, as the electrons give up energy to the r-f circuit, they do not slow down but move to a region of higher potential energy in the transverse d-c electric field. The efficiency of this type of oscillator is high. Theoretical efficiencies of 80 per cent have been predicted and in practice efficiencies of 20 to 40 per cent have been obtained. Tubes have been built with power outputs in the kilowatt range. The voltage-frequency characteristic of the M-type backward-wave oscillators is linear.

RC OSCILLATORS

38. Fundamentals. These oscillators differ in principle from *LC* oscillators in that an *RC* network replaces the tuned *LC* circuit as the coupling device between the output of the amplifier and its input. In certain *RC* oscillators, the performance of the network parallels that of the *LC* tuned circuit, and Q can be defined in a manner identical to that for tuned circuits. In other *RC* circuits no Q can be defined on the basis of any of the three accepted definitions for Q of an *LC* circuit. Brown[1] has proposed that $Q = \frac{1}{2}[d\phi/d\alpha]_{\alpha=1}$ be used, that is, as one-half the rate of change of phase with the fractional change of frequency at the operating point $\alpha = \omega/\omega_0 = 1$. By this definition values of Q range below and above unity. Morris[2] shows that defining Q in this manner leads to different values of Q depending upon the method of use of the *RC* network, *i.e.*, upon the terminal pair chosen for the output. He then proposes a mathematical concept, based on the differential equation of the circuit. This is most easily understood by an example. In Fig. 64
FIG. 64. Definition of Q as proposed by Morris.

$$\frac{V_2}{V_1} = \frac{R}{1/pC + R + pL}$$

where $R = R_1 + R_2$
$p = d(\quad)/dt$

[1] Brown, D. A. H., The Equivalent Q of RC Networks, *Electronic Eng.*, July, 1953, p. 294. Francini, Giuseppe, Evaluation of Oscillator Quality, *IRE Trans. Circuit Theory*, CT-2, No. 3, September, 1953.
[2] Morris, David, Q As a Mathematical Parameter, *Electronic Eng.*, July, 1954, p. 306.

Write the denominator in ascending powers of (pT), making the first term unity. Choose the time constant T so that the coefficient of $(pT)^2$ is unity. The reciprocal of the coefficient of (pT) is defined as Q. Then

$$\frac{V_2}{V_1} = \frac{pT/Q}{1 + pT/Q + (pT)^2}$$

where $T = \sqrt{LC}$
$Q = (1/R)\sqrt{L/C}$

If the similar ratios are formed for the several outputs indicated, the numerators of the expressions differ but the denominators remain the same. Defined in this way, Q is characteristic of the given assembly of components rather than of the particular
FIG. 65. If the circuit in (a) is rearranged as in (b), Q can be defined in conventional manner.

output that is taken from the components. Furthermore, the definition of Q can be extended to uses for which the conventional definitions are inapplicable.

For example, in the bridged T of Fig. 65a, Q cannot be defined according to any one of the three conventional definitions of Q. Following Morris's proposal Q can be defined.

The same components arranged as in Fig. 65b yield circuits in which Q can be defined in the conventional manner, $Q = f_0/(f_2 - f_1)$, where f_0 = resonant frequency and f_1, f_2 = frequencies at half-power points.

39. *CR* and *RC* Ladders. These are illustrated in Fig. 66a and b. For three sections up to six sections, the loss in either type is

No. Sections	Loss
3	1/29
4	1/18.4
5	1/15.4
6	1/14.1

The gain required in an amplifier to obtain oscillation is 1/loss.
FIG. 66. *CR* and *RC* ladders.
FIG. 67. *RC* ladder with graded sections.

Some improvement is obtained in the required gain if the successive sections are made of higher and higher impedance, as shown in Fig. 67, for three sections:

Multiplier a	Loss
1	1/29
2	1/16
3	1/12.8
4	1/11.4

40. Lead-Lag or Advance-Retard Networks. Little or no mention is made of "advance-retard" or "retard-advance" ladders in the literature. Papers show four
FIG. 68. The same frequency response is obtained from a Wien-bridge chain (*a*), a bridged-T (*b*), or a *CR* section followed by an *RC* section (*c*) or vice versa.

sections of "advance" (*CR*) or "retard" (*RC*) ladders, for example, with the idea that a total phase change of ±180 deg must be obtained. Many times, a net phase change of zero, produced by a ±90 deg shift followed by a ∓90 deg shift, leads to more desirable results.

The same performance as regards frequency response is obtained from the four elements of a *Wien-bridge* chain or of a bridged-T circuit by using them in a *CR* section followed by an *RC* section, or vice versa, as shown in Fig. 68.

41. Wien-bridge Oscillators. The Wien-bridge circuit is often used in *RC* oscillators, either in the series-parallel chain or with the chain as one half of a bridge with two resistors as the opposite half. Both are shown in Fig. 69*a* and *b*.

FIG. 69. Wien-bridge chain and a bridge form commonly used in *RC* oscillators.

Davidson[1] points out that, if the compensating resistor R is not used, the frequency of oscillation is

$$\omega_0 = \frac{1}{RC\sqrt{1 + R_A/R}}$$

where R_A is the source impedance.
FIG. 70. Compensation of an *RC* oscillator to make $\omega_0 = 1/RC$.

If the compensating resistor R is added (Fig. 70) and made equal to $R_A/2$, the frequency is $\omega_0 = 1/RC$ and precision decade resistors can be used to predetermine the

[1] Davidson, J. A. B., A Note on Precision Decade Oscillators, *Proc. IRE*, Correspondence, September, 1952, p. 1124.

frequency. At the higher frequencies, if R is slightly greater than $R_A/2$, some compensation for phase shift in the amplifier can be obtained.
Fig. 71. Phase-shifting circuit giving 90° phase shift.

42. Phase Inverters with *RC* or *CR* Networks. By use of a phase-inverter tube, an *RC* network which normally gives only ±45-deg phase shift can be made to give 90-deg shift. Two successive such stages provide 180-deg shift with a loss of only 4. The circuit is shown in Fig. 71, with the vector diagram. An oscillator based on this phase-shifting circuit is described by Frazer.[1] Rosenstreter[2] described it as part of "more complex apparatus" and Villard[3] described it as a tunable amplifier.

This idea is easily applied in making a source of voltage adjustable in phase, as described by Rao.[4]

A very good amplitude regulator, good from audio frequencies to 10 Mc or more, is another adaptation of the phase inverter, as shown in Fig. 72.

With *LC* and *RC* oscillators, where the driving amplifier has a large excess of gain, the use of this control will maintain the level practically constant. Using 6-watt 115-volt tungsten lamps, a balance will be obtained on the bridge, with about 1 volt on each half of the bridge, at which point the lamp resistances are about 370 ohms, which is the value of the fixed arms.
Fig. 72. Automatic amplitude regulator.

This form of *RC* phase shifter, applied in an oscillator, provides a feature which has been described only by Smiley and is given in a short summary below. If a voltage divider is used, a voltage of fixed phase can be obtained which is independent of frequency. As the oscillator is tuned over the range, the output of the first phase inverter is of constant phase but is displaced 90 deg from the input voltage. If these two voltages are applied to the horizontal- and vertical-deflection plates of a cathode-ray oscilloscope, a circular sweep is obtained which is maintained at all frequencies to which the oscillator is tuned. This is a very convenient arrangement for use in frequency measurements, particularly if the CRO has a radial deflection system. By adding a locking system, the oscillator can then be locked in fixed phase to standard frequencies, or multiples or submultiples thereof, giving great flexibility with highly accurate results.

A diagram of such an oscillator is given in Fig. 73.

43. Ultra-low-frequency Multiphase *RC* Oscillator. From the point of view of adjustment of frequency, range covered, control of amplitude, and purity of wave form, the three-phase *RC* oscillator has many points of interest.

The principle of the circuit as described by Smiley[5] is illustrated in Fig. 74.

One major factor in u-l-f oscillator design is the size and cost of the frequency-determining networks required to secure oscillations at frequencies so low that a single

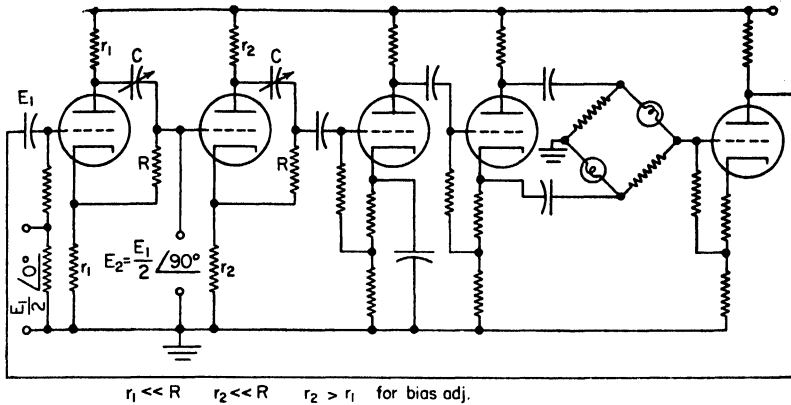
cycle may extend over an interval of 100 sec. Interfacial polarization in mica dielectrics becomes serious at frequencies below 20 cps.


Fig. 73. Oscillator circuit giving two voltages 90 deg apart at any frequency to which oscillator is adjusted.

An ingenious solution is that of obtaining the required effectively large values of capacitance through the use of small capacitances, of satisfactory properties, multiplied by means of the "Miller effect."

In the very simplified circuit of Fig. 74, the three RC circuits are disposed in a three-phase Y connection around the power supply. Since the sum of the phase currents at the neutral of a balanced three-phase Y is zero, no phase currents of oscillator frequency traverse the power supply. The oscillator is therefore independent of the impedance of the power supply. The supply thus requires only a minimum of filtering, regulation, and by-passing.

The oscillator is basically a three-stage reentrant d-c amplifier. Oscillation is at that frequency for which the phase shift is 60 deg in each of the three identical RC networks. At this frequency, each network attenuates the signal by 2. The d-c loop gain must be at least $2^3 = 8$. At d.c. (zero frequency), there is no RC phase shift so the d-c loop gain gives an attenuation of 18 db, making the system exceptionally stable against d-c drift.

The plate circuit voltage dividers R_v are ganged to effect tuning by variation of the Miller-effect gain with a minimum gain of 2 per tube. The system shown would have a 3 to 1 tuning range and, for the lowest frequency, the capacitors need to be but one-third the value necessary if the Miller-effect multiplication were not used.

Fig. 74. Three-phase RC oscillator having several interesting features.

The details of the operating circuit are rather involved and will not be covered here. For all such information, reference should be made to the article by Smiley.

A possible use of such an oscillator is in the measurement of transmission and phase performance by using a network of resistive components only to obtain a voltage adjustable in magnitude and phase with reference to a fixed voltage.

Through use of a Scott connection utilizing resistors, a two-phase output can be obtained which will generate a true circular sweep on a CRO at any frequency to which the oscillator is adjusted.

RELAXATION OSCILLATORS AND MULTIVIBRATORS

44. Introduction. The pulses used to time the sequential action of circuits in many modern communication systems are generated, shaped, and controlled in time duration by *RC* timed relaxation oscillators. The most common forms of these oscillators are the multivibrators and the blocking oscillator. All these circuits have in common the features of poor inherent frequency stability, ease of triggering (synchronization to another source of frequency), high output voltage (or current), and high harmonic content in their output wave form.
Fig. 75. Typical astable multivibrator, with wave forms in (*b*).
Fig. 76. Basic monostable circuit and wave forms.

Since these circuits are all similar in operation as far as stability, timing, and triggering are concerned, the next section will treat these common characteristics, and the succeeding section will discuss the individual characteristics of the more common forms of relaxation oscillators.

45. Multivibrator Basic Operation. The various forms of multivibrator circuits are most conveniently classified according to their time-stability characteristics. Usually there are two tubes involved in these circuits, and each tube has only two states of interest; it is either off or on. The off state is that in which the tube is biased beyond plate-current cutoff and in the on state the tube is commonly conducting near to zero-bias plate current. In the astable circuit, shown in typical form in Fig. 75, neither state of plate current can persist indefinitely. If tube V_1 is conducting, its plate current will drop a voltage in R_{L1} which is capacitively coupled via C_{c2} and R_{g2} to the grid of V_2. V_2 will be cut off until C_{c2} has discharged sufficiently to permit it to conduct. When V_2 begins to conduct, both tubes form a regenerative loop and V_1 is quickly switched off.[1] This state of affairs, with V_1 off and V_2 on, will persist

[1] Williams, E. M., D. F. Aldrich, and J. B. Woodford, Speed of Electronic Switching Circuits, *Proc. IRE*, **38**, 65, January, 1950. Chance, B., *et al.*, "Waveforms," M.I.T. Radiation Laboratory Series, Vol. 19, Chap. 5, p. 175, McGraw-Hill, 1949.

until C_{c1} discharges sufficiently to permit V_1 to conduct again. The timing sequence for this astable circuit is shown in Fig. 75*b*.

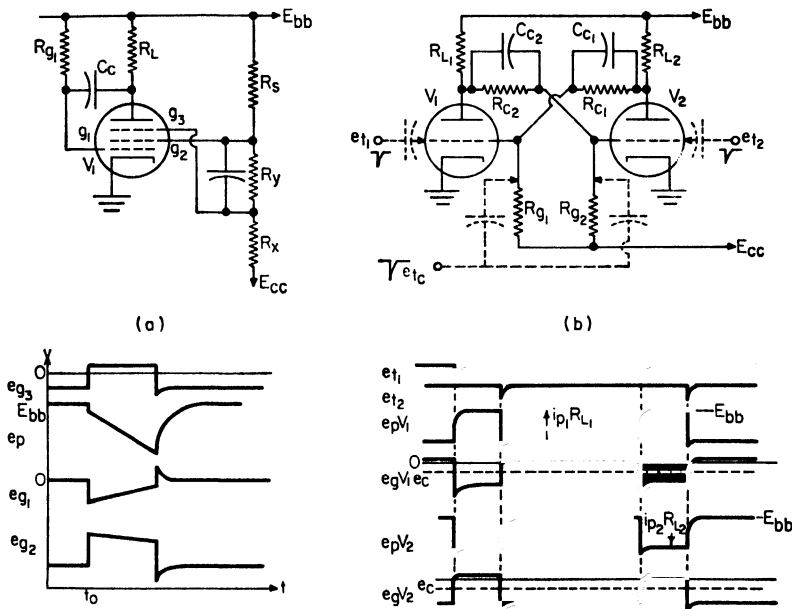
46. Monostable MV. Figure 76 shows a circuit revision which will convert the simple astable multivibrator to a *monostable* circuit. Without any external disturbance of the circuit, V_2 will be conducting near zero bias (grid returned to E_f through R_{g2} and cathode grounded). The drop in R_{L2} due to V_2 plate current is applied through R_{c1} and R_{g1} to keep V_1 biased beyond plate-current cutoff. This state is stable. Now upon the application of a triggering signal of appropriate polarity (a negative pulse is shown applied to the "on" grid in Fig. 76), the circuit will switch regeneratively. V_2 will go off and its rising plate voltage will drive the grid of V_1 up to the point where grid current will be drawn. The drop in plate voltage of V_1 is coupled via C_{c2} and R_{g2} to the grid of V_2 and will keep V_2 off for a time determined


FIG. 77. (*a*) Simple phantastron circuit with wave forms. (*b*) Bistable circuit.

by the $R_{g2}C_{c2}$ time constant and V_1 plate swing. When C_{c1} discharges sufficiently to permit V_2 to conduct, the circuit will regeneratively switch back to its original stable state where it will remain until triggered. This timing and triggering sequence can be followed in Fig. 76*b*.

A second major class of multivibrators, usually having monostable characteristics, consists of those circuits which are timed by a Miller-effect sweep circuit.[1] The simplest form of this monostable circuit is the phantastron shown in Fig 77*a*.[2] This circuit form has many variations to fit it to particular applications. Chief among these are the cathode-coupled and cathode-follower-coupled phantastrons and the sanatron circuits.[3]

The most striking difference between the phantastron circuit of Fig. 77*a* and the astable and monostable circuits of Figs. 75 and 76 is in the means of timing. In the circuit of Fig. 77*a*, timing is based on the Miller effect.

[1] Chance *et al.*, *op. cit.*, pp. 195–204, 279.
[2] Millman, J., and H. Taub, "Pulse and Digital Circuits," p. 222, McGraw-Hill, 1956.
[3] Chance, *op. cit.*, p. 279.

The tube shown in Fig. 77*a* is one of those in which both grids 1 and 3 are sharp cutoff (6AS6, 5915, etc.). Normally, plate current is off because the high screen-grid current lowers the grid 3 below its base. Under these conditions, C_c will be charged to E_{bb} with G_1 drawing current through R_{g1}. Suppose the circuit is triggered by, say, a negative pulse on grid 1. Screen current is momentarily reduced, raising the screen voltage and hence the voltage at grid 3. This action is regenerative, for when plate current comes on, the drop across R_1 lowers grid 1. A negative step appears at the plate; and, since the voltage across C_c cannot change instantaneously, the same negative voltage step appears at G_1. G_1 obviously cannot cut off plate current; so an equilibrium is established at some low value of plate current. As C_c discharges, grid 1 tends to become more positive, increasing plate current and decreasing the plate voltage, replacing most of the lost charge on C_c. The equation for the plate voltage as a function of time depends upon R_gC_c and upon the gain from grid 1 to plate, K, the actual equation being[1]

$$e_p(t) = KE_{bb}\left[1 - \epsilon^{\frac{-t}{(1-K)R_gC_c}}\right]$$

which, for K large with respect to 1, reduces to the linear term of a series:

$$e_p(t) = -\frac{E_{bb}}{RC}t$$

Therefore, during the astable portion of the multivibrator cycle, the plate voltage runs down nearly linearly as grid 1 voltage increases. This action is terminated when the plate voltage "bottoms" and space current switches to the screen, lowering grid 3 voltage so that the plate current regeneratively switches off. After the astable portion of the period, C_c must recover its charge via the grid 1 cathode space and R_1. This exponential recharge is very similar to the recovery of the astable multivibrator of Fig. 75.

One obvious means of controlling the astable period of the phantastron is to control the plate voltage independently of the screen voltage. This is advantageous since the time to run down is linearly related to the starting-plate voltage.

The cathode-coupled version of the circuit eliminates the necessity for a negative supply in a fashion similar to the cathode-coupled monostable shown in Fig. 82. Recovery time can be improved by driving the coupling capacitor through a cathode follower. These various special circuit forms are analyzed in detail in Chance and in Millman and Taub.

47. Bistable MV. The bistable circuit constitutes the third major class of MV. A basic circuit is shown in Fig. 77*b*. As its name implies, the bistable circuit has two positions of stable equilibrium in which it can remain indefinitely. In order to be useful, it must be triggered. Let us first examine the stability conditions and then consider how the circuit can be triggered. V_1 is conducting and its low value of plate voltage can be caused to keep V_2 off by correctly choosing the R_{c2}, R_{g2} voltage divider and bias voltage. Now, if the circuit is symmetrical $R_{L2} = R_{L1}$, $R_{c1} = R_{c2}$, and $R_{g1} = R_{g2}$, and if V_2 were on, V_1 would be off. The circuit can be caused to trigger in either of two ways. Referring to Fig. 77*b*, triggering pulses can be applied separately to each grid, or in common to both grids. If trigger pulses are applied to both grids simultaneously, the different charges on C_{c1} and C_{c2} cause the circuit to change state, and under these circumstances, the circuit will divide the input frequency by 2.

48. Blocking Oscillator. A typical blocking-oscillator trigger circuit is shown in Fig. 78. By either grounding R_g or returning it to a bias supply adequate to cut the tube off, the circuit can be caused either to oscillate at the frequency determined by C_cR_g or to respond to an input positive triggering pulse.

To understand the basic principles of operation, assume that V_1 has been off for some reason and just begins to conduct. The rising plate current induces a voltage in the secondary of T_1 so as to drive the grid of V_1 positive, causing V_1 to conduct more

[1] Chance, *op. cit.*, p. 279.

heavily. This regenerative action quickly drives the grid highly positive. A typical situation finds the grid and plate at nearly the same potential at around half the plate-supply voltage. The heavy grid current charges C_c, and the voltage across C_c will go negative with respect to ground. The build-up of plate current in V_1 is limited by the primary inductance of T_1 and is at first nearly linear so that a nearly constant positive voltage is present at the grid. When C_c is charged to nearly the induced grid voltage, any decrease in plate current will cause the grid voltage to fall and the circuit will then switch off regeneratively. The charge on C_c must now be lost via R_g before conduction can begin again. The exact operation of the circuit is not nearly so simple as pictured here. Actually, there are several possible modes of operation for the circuit depending upon the transformer parameters and capacitance C_c.[1]

FIG. 78. Basic blocking-oscillator circuit and wave forms.

When the blocking-oscillator circuit is self-oscillatory, the free-running period is the sum of the "on" time and the time set by the exponential discharge of C_c through R_g (see following section). Since the "on" time is usually very brief (0.1 to 5 μsec), the period is very near to the time set by C_c, R_g.

RELAXATION OSCILLATOR CIRCUIT DESIGN

49. Basic Timing Equations. All the switching circuits described above have their
FIG. 79. Illustration of the timing principle.

astable periods timed in an identical way. That is, a tube goes into conduction and applies a step of voltage to a capacitor, which then must discharge to the critical point where the second tube involved (the same tube in the case of the blocking oscillator) can conduct. Figure 79 illustrates this timing operation. The driving wave form (magnitude E_i) is usually the plate swing of a tube. E_0, the initial value of voltage at which the timing grid is maintained, is usually zero and can be omitted. After the driving plate comes on, the grid voltage swings negative by the same amount as the plate. The equation for the grid voltage with time is given by[2]

$$e_g = E_f + (E_0 - E_i - E_f)\epsilon^{-\frac{t}{R_gC_c}} \tag{5}$$

Now at time T_p, the instantaneous grid voltage is $-E_c$ and

$$-E_c = E_f + (E_0 - E_i - E_f)\epsilon^{-\frac{T_p}{R_gC_c}} \tag{6}$$

[1] Benjamin, R., Blocking Oscillators, *J. IEE*, **93**, Part IIIA, No. 7, 1159, 1946. Millman and Taub, *op. cit.*, Chap. 9, pp. 253–285.

[2] Chance *et al.*, *op. cit.*, p. 178.

Solving this equation for the time,

$$T_p = R_g C_c \log_\epsilon \frac{E_f + E_i - E_0}{E_f + E_c} \tag{7}$$

This is the basic MV timing equation. It says that the period of the multivibrator due to the time constant is linearly proportional to $R_g C_c$ and proportional to the natural logarithm of the quantity given by the final value toward which the capacitor is discharging, plus the plate swing, divided by the final value of grid voltage plus the critical grid voltage at which the tube will again switch state. When the final value is ground and when the initial value is ground, this equation reduces to

$$T_p = R_g C_c \log_\epsilon \frac{E_i}{E_c} \tag{8}$$

and the logarithmic multiplier is just the driving swing divided by the cutoff voltage.

In preparation for the practical design of multivibrators, several important facts can be learned from this equation. First, there is a first-order independence of the period with changes in the plate supply for the circuit. This is because both the plate swing of the driving tube and the cutoff of the driven tube are directly proportional to plate-supply voltage: $E_c = E_{bb}/\mu_{co}$, and $E_i = E_{bb}\bar{r}_p/(\bar{r}_p + R_L)$, where $\bar{r}_p$ is the static plate resistance of the driving tube. Using these relationships, Eq. (8) becomes related to the tube and load resistor.

$$T_p = R_g C_c \log_\epsilon \frac{\bar{r}_p \mu_{co}}{\bar{r}_p + R_L} \tag{9}$$

The stability of timing is therefore proportional to variations in these quantities, of which $\bar{r}_p$ for the tube is usually the largest variable during the life of the tube. Methods of stabilization of the period against this variable are given in Sec. 57.
FIG. 80. (*a*) Practical astable multivibrator connected for frequency division. (*b*) Idealized timing wave form showing principles of frequency division.

50. Frequency Division Using Synchronized Multivibrators. By adding pulses at a higher frequency to the grid-timing wave form, the astable or monostable multivibrators can be locked to some submultiple of the higher frequency. Figure 80*a* shows an astable multivibrator circuit similar to Fig. 75 connected[1] as a frequency divider. Figure 80*b* is a linearized drawing of its grid-timing wave form showing the principles of division. Triggering pulses of amplitude e_t with period T_t are added to the timing wave form. (The usual procedure is to add negative triggering pulses to the "on" grid of the multivibrator as shown in Fig. 80*a*.) In the example shown, the division ratio is 4. In designing the MV to divide most reliably the quantities which must be exactly determined are the trigger amplitude as determined by the magnitude of the plate swing E_i and the division ratio R. Examination of Fig. 80*b* will permit one to write

$$E_t = \frac{2(E_i - E_c)}{2N + 1} \tag{10}$$

A simple logical argument will show that this is the correct trigger amplitude for

[1] Shenk, E. R., Multivibrator, Applied Theory and Design, *Electronics*, **17** (1), 136; (2), 140; (3), 138, 1944. Millman and Taub, *op. cit.*, Chap. 12, pp. 355–372.

maximum stability. The results of this derivation are equally applicable in the actual case where the timing wave form is an exponential.

The two quantities which tend to vary over the life of the frequency-dividing MV are E_i, the magnitude of plate swing, and the slope of the timing wave form set by R_g and C_c. Suppose the driving tube ages; E_i will decrease by just $\frac{1}{2}e_t$, at which time the peak of the $N - 1$ pulse will reach E_c and the circuit will fail. If e_t were *larger* in amplitude, E_i could not decrease as much before failure. Now suppose that for some reason E_i increases. It can increase by exactly $\frac{1}{2}e_t$ before the division fails by jumping to $N + 1$. If e_t were *less* in amplitude than Eq. (6) dictates, the unit will fail before E_i increased by $\frac{1}{2}e_t$ by the peak of e_t not passing through E_c. This same argument holds true for changes in R_gC_c, causing the timing slope to change with E_i fixed at its correct value.

Now that the optimum triggering conditions have been derived, it is apparent just how much variation in E_i and slope can be tolerated before a divider will fail. In the linearized example of Fig. 80*b*, with $N = 4$, suppose $E_i - E_c$ is 100 volts; then e_t should be 22.2 volts. The division will fail when E_i decreases by about 11 volts. Thus, about ± 10 per cent can be tolerated in the plate swing of the driving tube with a 4:1 division. The fact that the timing wave form is truly exponential *decreases* this tolerance because the slope near the critical voltage is *lessened*. Apparently, to build multivibrators to divide safely by ratios of even 4:1 or 5:1, precautions must be taken to stabilize the driving plate current and to determine slope correctly either by using close-tolerance components or by exactly adjusting the R_gC_c product. Since even new tubes vary by as much as 20 per cent in plate current and μ_{co}, to divide by 5:1 on each side of an astable MV requires adjustment of both RC products and the trigger amplitude. Again the methods of stabilizing plate current in Secs. 53 to 57 should be applied in the design of reliable frequency-dividing multivibrators.

51. Harmonic Generation. The abrupt changes in voltage, occurring in all forms of the trigger circuits discussed here, when switching from one state to another make them useful as sources of harmonics for frequency multiplication, for heterodyne calibration, etc.[1] A great deal must be known about the circuit and its wave forms before the exact harmonic spectrum can be predicted by Fourier analysis.[2] In general, if the maximum extent of harmonic spectrum is desired, the circuit must be designed to produce one voltage transition in the minimum possible time. For example, design of the switching circuit to produce square waves will yield an output spectrum with a minimum of even-order harmonics.

TRIGGER CIRCUIT DESIGN

52. Basic Requirements. Any one of several qualities of the trigger circuit can predominate to dictate the practical design procedure. The circuits must all be designed to meet the basic requirements for correct operation as outlined below, but these basic requirements must be modified to fit the circuit to the system in which it is a component. Practical requirements which usually dictate circuit design individually or in combination are:

1. Wave shape (rise or fall time, flatness, etc.)
2. Speed (of either transitions or maximum repetition rate)
3. Output voltage
4. Output impedance

Together with these basic requirements is that of reliability. With the increasing complexity of today's electronic systems, this requirement often becomes predominant, limiting performance in all other categories. Designing reliability into the trigger circuit goes much further than just choosing the best components and most reliable tube types. Wherever the circuit can be made to meet its other basic requirements,

[1] Frank, R. W., A High-precision Calibrator for Frequency and Time, *Gen. Radio Experimenter*, **31**, 4, June, 1956.

[2] Kandoian, A. G., *et al.*, "Reference Data for Radio Engineers," pp. 1019*ff.*, Federal Telephone and Radio Corp., 1956.

the residual performance can all be used up in obtaining reliability. When a particular circuit cannot meet its performance requirements with the desired margins for tube aging, or component drifts or tolerance, a better tube, more costly components, or even another stage must be added. Finally, when the best available tubes have been applied, reliability must limit maximum attainable performance or vice versa.

53. Design of the Astable Circuit. The astable MV is commonly used as a simple and economical oscillator, or as a frequency divider. The maximum frequency and the stability of the output frequency (or in the case of the frequency-dividing MV the reliability of the division as the tube ages) are the most important criteria.

A straightforward qualitative analysis of the circuit dictates the design procedure. Refer again to Fig. 75. The plate current of the "on" tube produces a drop in the load resistor R_{L1} which keeps the "off" tube off for a time determined by Eq. (7). After the second tube switches on, turning the first off, the coupling capacitor and stray capacitances must recharge via R_{L1} and the grid resistance of the "on" tube. This recharge cycle will limit the maximum frequency for a given C_c. To obtain maximum frequency, C_c must be lowered as far as practical, a limit being imposed by the input capacitance at the grids which will reduce the timing voltage. Having lowered the C_c, one must then decrease R_L and use a higher-perveance tube to maintain an adequate plate swing. A practical limit to this procedure is obtained when the best tube has been used. A typical circuit in the form of Fig. 80 for operation at around 1 Mc uses a type 5687 tube with 5,100-ohm plate resistors, C_c = 33 $\mu\mu$f, and R_g = 43,000 ohms. With a 150-volt power supply, a plate swing of 95 volts will be obtained. In this limiting example, the frequency stability of the circuit over the life of the tube is poor. Figure 81 shows what happens to the plate swing as the tube ages and $\bar{r}_p$ doubles at end of life. The end-of-life plate swing is 70 volts, and from Eq. (7) the frequency will rise by about 22 per cent. A means for stabilizing this circuit against tube aging is given in Sec. 57.

FIG. 81. Characteristics of type 5687 tube showing effect of aging.

At lower frequencies, much more stable operation is possible.[1] Consider the design of a symmetrical multivibrator for 10 kc. R_L is chosen at 100,000 ohms; this sets C_c at 125 $\mu\mu$f if four time constants of recovery of plate voltage for the off tube are allowed. R_g must then be 680,000 ohms. Even if the tube chosen is a 12AU7, the plate swing for a new tube is 140 volts, for an end-of-life tube 130 volts, and the "unlocked" frequency will only vary about 4.5 per cent down as $\bar{r}_p$ doubles. With this sort of stability, the circuit could be used to divide frequency reliably up to 20:1, if no other variables but $\bar{r}_p$ for the tube are considered!

54. Design of Monostable Circuits. The timing portion of the cycle of the monostable circuit obeys the same rules as the astable circuits just discussed. Both the monostable and bistable circuits must fulfill certain d-c conditions for proper operation over the life of the tubes. The grid of V_1 in the monostable circuit of Fig. 76 under all conditions of component tolerance, supply variation, and tube aging must be maintained beyond cutoff. This can be assured by choosing an R_{L2} appropriate

[1] Harris, C. C., The "Hard-bottoming" Technique in Nuclear Instrumentation Circuit Design, *IRE Trans. Nuclear Science*, NS-3 (2), 5, March, 1956.

to the desired output voltage, impedance, or rise time (thus establishing, by this combination, the tube necessary to meet both output-voltage and band-width requirements). Now having V_2 and R_{L2}, the tube can be aged in imagination to the desired "end-of-life" conditions, say to $\bar{r}_p$ doubled. This end-of-life plate swing and the worst combination of component tolerances must establish cutoff in V_1. At the same time, when V_2 is off, V_1 must be brought up to the desired level of plate current (usually zero bias). This swing places a further requirement on R_{L2} or the negative supply. R_{L1}, R_{g2}, and C_c can be chosen on the same basis of recovery time and astable timing as for the astable circuit.

FIG. 82. Circuit and wave forms of cathode-coupled monostable multivibrator.

The circuit of Fig. 82 shows a somewhat more sophisticated monostable. This cathode-coupled circuit is the most commonly encountered form in practice.[1] It both eliminates the negative supply and stabilizes the timing plate swing of V_1 so long as V_1 is not permitted to swing into grid current. In its stable quiescent condition, V_2 is on and in grid current. The zero-bias plate current of V_2 holds the cathode potential at a sufficiently high level that V_1 is off. This must be ensured even at "end of life" for V_2. When the circuit is switched, say by application of a negative pulse at the plate of V_1, V_2 goes off and V_1 comes on as the cathode voltage falls. As long as V_1 is not in grid current, the effective resistance seen looking back into its plate is

$$R_{\text{eff}} = \bar{r}_p + R_k(1 + \mu) \tag{11}$$

With freedom to choose R_k and with the choice of a high-μ tube, $R_k(1 + \mu)$ can be made very large with respect to $\bar{r}_p$ and variations in $\bar{r}_p$ will cause very little variation in plate current.

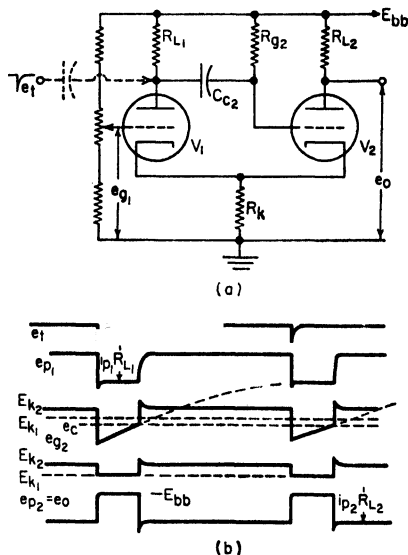
This circuit has another valuable characteristic. Because of the linear relationship of the control grid voltage and the plate current of V_1, the timing of the astable period is highly linear with respect to the control-grid voltage.

In the design of this form of monostable MV, R_{L2} is chosen to provide the desired output voltage. $R_{L2} + R_k$ with V_2 in grid current established by R_g are chosen to set the operating current for V_2 within its ratings. As usual the choice of impedance level and the tube used will determine the switching speed. $R_{L1} + R_k$ with the bias on V_1 when it is on establish the plate swing of V_1. This is the timing swing E_i of Eq. (8). It is now only necessary to choose C_c and R_{g2} to establish the astable period.

After the astable period terminates, C_c must reestablish its charge through the grid-cathode resistance of V_2, R_k, and R_{L1}. R_k, R_{L1}, and C_c should be set so that at least four time constants,

$$4(\bar{r}_g + R_{L1} + R_k)C_c \tag{12}$$

are allowed before retriggering at the highest repetition rate desired; otherwise there will be a large effect on the timing.

55. Bistable-circuit Design. Perhaps no other circuit in use in present-day electronics has had so much effort spent in attaining optimum design as the bistable multi-


[1] Chance *et al.*, *op. cit.*, p. 170. Millman and Taub, *op. cit.*, pp. 187*ff*.

vibrator.[1] By consulting the literature, the circuit designer can obtain a design optimized for the particular plate swing, speed, or life desired.

As usual, the speed is determined by the quality (g_m) of the tube chosen. A 12AU7 can deliver 100-volt plate swings at speeds up to 100 kc quite reliably, a 5687 up to 1 Mc, and beyond that, high-quality pentodes can be operated up to speeds in excess of 10 Mc with small plate swings. Special techniques have produced bistable circuits capable of operation at speeds in excess of 50 Mc.[2]

Where a negative supply is available, a bistable circuit of simplest form (Fig. 77) can be designed. Having chosen the tube and its load resistor for the desired plate swing, the R_cs and R_gs are chosen to ensure that (1) when the driving tube is off, the driven tube will be in grid current, and (2) when the driving tube is on, the driven tube will be driven beyond plate-current cutoff. Both conditions (1) and (2) must be met under the worst possible circuit conditions of resistance tolerance, expected tube aging to "end of life," initial variations in the cutoff μ for the tubes, and supply variations. All these variations require that the *average* tube be highly overdriven and this will reduce the switching speed. Therefore, in attaining maximum speed, it is customary for as many of these variables as possible to be eliminated or reduced. Often it is necessary and economical to use precision resistors in the cross-coupling networks, regulated supplies, and specially built (computer) tubes whose μ_{co} and initial-plate-current balance are carefully controlled.

The most common form of the bistable eliminates the negative supply by using a common cathode resistor. The drop across this resistor is the value of the negative supply and the design can proceed as described in the last section. $R_k + R_L$ is first laid out as a load line on the tube characteristics and the desired plate current and output voltage are established. The values of the cross-coupling dividers are then set to ensure zero bias and cutoff d-c conditions under the worst expected set of circuit conditions.

56. Triggering of Bistable Circuits. As stated in the introductory paragraphs, there are two distinctly different ways in which it is desirable to trigger the bistable circuit. It is often desired only to set the circuit into one state or the other. In Fig. 77, a negative pulse T_1 will set V_1 off and V_2 on, while negative pulse T_2 will reverse the state. This type of "single-ended" triggering requires very little a-c coupling via C_{c1} and C_{c2} from plate to grid and these capacitors can be set at a value to just compensate for the input capacitance of the tubes. The second sort of trigger injection is that in which the trigger pulse is applied to both grids simultaneously. The circuit is said to be "complemented." It is this form of triggering which must be used when the circuit is to divide the input trigger rate by 2. In this case, the stored charge on C_{c1} and C_{c2} causes the circuit to change from one state to the other with each trigger. The capacitors must be increased to give an effective *overshoot* at each grid lasting for a longer time than the trigger pulse. Therefore, after each triggering pulse, the grid transient puts a larger voltage on the grid than that predicted by the d-c design. It is the recovery of this transient which will now limit the maximum speed at which the unit can be driven with a given trigger pulse. The cross-coupling capacitors must thus be chosen to permit reliable triggering under the worst trigger-pulse amplitude conditions, while still not limiting the maximum speed below that desired. The maximum speed due to the recovery of this transient can be raised by reducing the time constant R_cC_c at the expense of increased power dissipated in the cross-coupling network and a lowered effective value of E_{bb}.

57. Stabilized-plate-current Multivibrators. In all the multivibrators discussed in the preceding paragraphs, the demands for increased speed call for a lowering of circuit impedance levels and tubes of higher perveance to provide the desired plate swings. With impedance levels approaching the static plate resistance, the plate swing and therefore the timing or d-c stability become highly dependent on plate resistance, and thus upon tube aging. In Sec. 54 it was pointed out that the timing due to the plate swing of the left-hand tube of Fig. 82 was nearly independent of the

[1] Millman and Taub, *op. cit.*, Chap. 5, pp. 140–173. Ritchie, D. K., The Optimum DC Design of Flip-flops, *Proc. IRE*, **41** (10), 1614, November, 1953. Pressman, R., How to Design Bistable Multivibrators, *Electronics*, April, 1953, p. 164. Paivinen, J. O., and I. L. Averbach, Design of Triode Flip-flops for Long-term Stability, *IRE Trans. PGEC*, **EC-2** (2), 14, June, 1953.

aging characteristics of the tube so long as the tube *did not* reach zero bias, the change of plate current with $\bar{r}_p$ being given by Eq. (11).

This principle can be extended to all the circuits of this class. A current-stabilized astable circuit is shown in Fig. 83. The grids are prevented from reaching zero bias during the expected tube life by the diode grid clamps. Crystal diodes can be used so long as the grid impedance levels are sufficiently low that back resistance can be neglected at all temperatures. The desired timing stability can be designed into the circuit by choosing the R_k appropriate to Eq. (11).

FIG. 83. Current-stabilized astable multivibrator.

The extension of this principle to the bistable circuit and other monostable forms is obvious. In all forms of the stabilized circuits, the concomitant advantage of a stabilized amplitude for the output wave form is gained.

Any other means of stabilizing the plate swing of the timing tube will, of course, stabilize the circuit against tube variations. Often because of the undesirability of adding capacitance at a grid or the desirability of using semiconductor diodes, it is possible to stabilize a plate swing by d-c clamping techniques. The disadvantage of this system lies in the low impedance required of the clamp supply voltage and the necessary additional power. If many similar circuits are used in the system, a separate power supply for the clamps can be an economical solution.

58. Blocking-oscillator Design. The design of a satisfactory and reliable blocking-oscillator circuit hinges primarily on the transformer used. The design of pulse transformers is beyond the scope of this section, and the reader is referred to the literature.[1] Many manufacturers of pulse transformers publish a recommended circuit and offer a line of pulse transformers to produce a wide gamut of possible pulse durations when these transformers are used in their circuit. As a general rule, the most desirable tubes to be used in a blocking oscillator have a low ratio of control-grid current to plate current when the control grid is highly positive. These are usually low-mu tubes, such as the 12AU7, 5687, 6350, etc.

There always arises the question of how the tube will stand up under the heavy instantaneous pulses of current encountered in blocking-oscillator service. Very few life-test data are available for this class of service. Experience indicates that, so long as the pulses are sufficiently brief that space charge is not exhausted, only the usual ratings of average cathode current, element dissipations, and peak voltages need to be met. For the most conservative designs, tubes such as the 6350 and 6463, which are assigned peak current ratings for all elements, can be used with confidence.

TRANSISTOR OSCILLATORS

Transistor oscillators may be divided into two different classes, negative-resistance oscillators and feedback oscillators. Oscillators of the first type make use of the negative driving-point impedance exhibited by point-contact transistors with certain circuit arrangements. While oscillators of this type have been considered at some length,[2] only the mechanism of obtaining the negative resistance is different from previously known oscillators of this type, and as junction-transistor characteristics are steadily improved, negative-resistance transistor oscillators are dwindling in importance.

59. Transistor Feedback Oscillators. In these circuits some of the output of an amplifier is fed back to its input in the proper phase to maintain oscillations. Transistor feedback oscillators are in many ways analogous to vacuum-tube feedback oscillators, but there are a few important differences:

1. The transistor generally has a low input impedance and behaves as a current amplifier, so that it is usually necessary to feed back a *current* of the proper phase rather than a *voltage*. As a very simple example, consider the phase-shift oscillator of Fig. 84. In the vacuum-tube case, the voltage across the last shunt resistor in the phase-shift network is applied to the grid of the first tube as in Fig. 84*a*, while in the transistor oscillator, the current in the last shunt resistor flows into the base of the first transistor as in Fig. 84*b*. When feedback is obtained from a tap on a tuned circuit, the low and generally nonlinear input impedance of the transistor must be considered.

FIG. 84. Phase-shift oscillators. (*a*) Tube type; (*b*) circuit using transistors.

2. Transistor dynamic characteristics are very linear up to the point of abrupt discontinuity (reverse collector bias or emitter-current cutoff) so that some external amplitude-limiting arrangements are necessary in almost all cases for low-distortion sine-wave output. Such power-sensitive devices as thermistors or lamp bulbs[1] have been included in oscillator circuits in such a way as to effectively decrease the positive feedback as the oscillation amplitude increases. Very effective amplitude control is obtained when such a control element is included in the Meacham bridge[2] circuit. Amplitude control of class C oscillators has been obtained by means of a bias voltage proportional to the output amplitude which is fed back to decrease the conduction angle as the output amplitude increases.[3]

3. Phase shift occurs in the current gain of a transistor at much lower frequencies than in the transconductance of a vacuum tube. Therefore, in transistor r-f oscillators the phase shift required of the feedback network may be any value from 0 to 360 deg. This effect also acts to decrease the span of the upper ranges of variable-frequency oscillators.

Transistor counterparts of nearly all types of vacuum-tube oscillators have been constructed. Crystal-controlled transistor oscillators have been built for frequency-standard purposes[2,4] and in this use transistors have the advantage, because of their

[4] Sulzer, P. G., Transistor Frequency Standard, *Electronics*, **26**, 206, May, 1953.

small size and low power requirements, that the entire oscillator circuit can easily be placed in a constant-temperature environment. A transistorized f-m signal generator has been constructed for the frequency range 20 to 100 Mc.[1] It makes use of a transistor oscillator operating at frequencies up to 33.3 Mc and a harmonic selector (frequency multiplier). Modulation is accomplished by a reactance transistor. An interesting application of transistor oscillators has been in the field of d-c to a-c conversion.[2] Such circuits make use of a push-pull square-wave oscillator wherein high over-all efficiency and very high collector efficiencies are obtained. Multivibrators[3] and blocking oscillators[4] have also been constructed with transistors. This circuit of a simple free-running MV is shown in Fig. 85. In this case there is a very close analogy to the corresponding tube circuits.
Fig. 85. Free-running transistor multivibrator using *p-n-p* junction transistors.

LOCKED OSCILLATORS

60. Frequency Dividers. Any of the *RC* oscillators previously described is capable of being locked to a control frequency signal, either of the same frequency or of a higher frequency. This effect is sometimes most troublesome if the filtering of the power supply is not adequate. The *RC* oscillator may then show definite locking ranges at multiples or submultiples of the line frequency.
Fig. 86. Phase-shift oscillator used as a frequency divider.

In Fig. 86 is shown an arrangement for division from a 1,800-cycle tuning fork to 60 cycles. Two stages are used, one dividing by 5 and one by 6. The circuits are identical; only the values of *C* and *R* are altered.

61. Locking Circuits. More rigid control could be obtained by use of a tube as a voltage-controlled resistance element whereby the oscillator frequency can be changed by changing the grid voltage. If the grid voltage is derived from the output of a phase detector, then rigid control of the oscillator frequency can be obtained.

Since properly operating oscillators have no great harmonic content, it is necessary to generate harmonics by use of external circuits if reliable control of the oscillator is required when the oscillator fundamental frequency is a submultiple of the control frequency.

[1] Hupert, J. J., and T. Szubski, Transistorized F-m Signal Generator, *Electronics*, **28**, 133, February, 1955.
[2] Uchrin, G. C., and W. O. Taylor, A New Self-excited Square-wave Transistor Power Oscillator, *Proc. IRE*, **43**, 99, January, 1955.

[4] Linvill, J. G., and R. H. Mattson, Junction Transistor Blocking Oscillators, *Proc. IRE*, **43**, 1632, November, 1955.

A simple means, which is many times sufficient, is shown in Fig. 87. The voltage-controlled resistor could be used to replace R_2 of Fig. 86, for example.
FIG. 87. An *RC* oscillator phase-locked to a reference frequency source.

Such a control system is very useful in obtaining submultiples of a standard frequency down to values in the range of 1 to 10 cycles.

For certain purposes, it would be desirable to lock a heterodyne frequency meter or signal generator to some standard frequency to avoid the necessity of continually checking the frequency to avoid errors of measurement due to drift.

Where oscillators draw grid current, a d-c control voltage can easily be applied through a series resistor R as indicated in Fig. 88. If R is of the order of R_g, an appreciable part of the d-c control voltage can be applied to the oscillator grid. Change of the d-c bias affects the frequency slightly, sufficient to give locking over a range generally more than adequate to maintain the oscillator in control for all ordinary temperature or supply-voltage variations over periods of an hour or more.
FIG. 88. Phase-locking a frequency meter to a reference frequency source.

BEAT-FREQUENCY OSCILLATORS

Beat-frequency oscillators are oscillator circuits in which the output signal is produced by beating together two signals differing in frequency by the output frequency. The two beating signals can be obtained from *LC* tuned oscillators, *RC* oscillators, or combinations of various types of oscillators. Among the various types of oscillators which are often used in beat-frequency oscillators are (1) two *LC* tuned oscillators, (2) one *LC* tuned and one crystal-controlled oscillator, (3) two klystrons. Other combinations, such as two *RC* oscillators or one *RC* oscillator and one crystal-controlled oscillator, sometimes occur, and at least one oscillator used three *LC* tuned oscillators to produce two beat notes simultaneously. The basic elements of a BFO are shown in the diagram of Fig. 89.

FIG. 89. Basic beat-frequency oscillator.

62. BFO Characteristics. Two distinct virtues not obtainable in other oscillator circuits are possessed by BFOs: (1) the output frequency can be made to cover many octaves of frequency on one dial range, and (2) a calibrated incremental frequency adjustment can be provided at any frequency by adding a small calibrated tuning adjustment to the fixed oscillator. The first feature is extremely valuable in work requiring recording of characteristics throughout the audio, or even the entire video, portion of the spectrum at one sweep; the second provides means for investigat-

ing narrow-band phenomena such as filter characteristics, which may occur at frequencies distributed throughout the spectrum covered by the oscillator.

Many other special tuning characteristics, such as multidecade logarithmic and linear-frequency scales including zero, are obtainable.

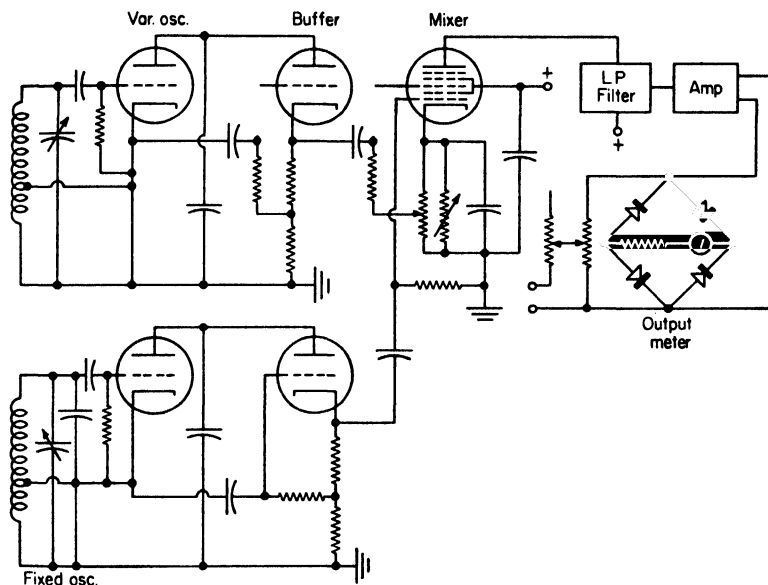
A constant output level can be obtained either by applying a-g-c techniques or by making the fixed oscillator operate to inject a smaller signal into the mixer than that from the variable oscillator. In the latter case, the beat note is controlled in amplitude by the smaller signal, which is fixed, and hence a constant-amplitude beat note results. Equally constant output results if both fixed and variable oscillators give constant input to the mixer at all settings of the dial.


FIG. 90. Typical beat-frequency oscillator.

Harmonic distortion in the beat note results mainly from two causes, (1) distortion in the beating-oscillator wave forms, and (2) distortion in the mixing process. Distortion in the beating-oscillator wave forms becomes especially large if the oscillators are not adequately isolated by shielding and power-supply filtering when the oscillators are operating at frequencies giving low-frequency beat notes. Oscillators with large amounts of harmonic distortion in their wave forms tend to synchronize or lock under such conditions.[1] The a-f beat note produced by such unstable oscillators usually contains much harmonic distortion. The remedy is to reduce the harmonics in the oscillators and to isolate each from the other electrically. Distortion in the mixing process may be reduced by employment of a low-distortion mixing stage or by resort to balanced modulators to suppress unwanted higher-order mixing distortion products. The mixer stage shown in Fig. 90, using a 6SA7 tube, may be adjusted to produce a sine wave of total distortion under 0.08 per cent. Such a result requires ability to adjust the magnitudes of each of the beating voltages and of the bias values on each of the input grids. However, the purity of wave form easily obtainable by this means is equalled only by elaborate feedback systems in *RC* oscillators.

[1] Rouche, N., Étude du régime de synchronisation de deux oscillators couplés, *Bull. sci. AIM*, January, 1956, No. 1.

Oscillator beat notes other than the desired beat note, commonly called "birdies," are generally the result of harmonic distortion in one or both of the beating oscillators but are sometimes the result of distortion in the mixer or of undesirable pass bands in the filter or amplifier combined with small amounts of distortion in the desired beat note.

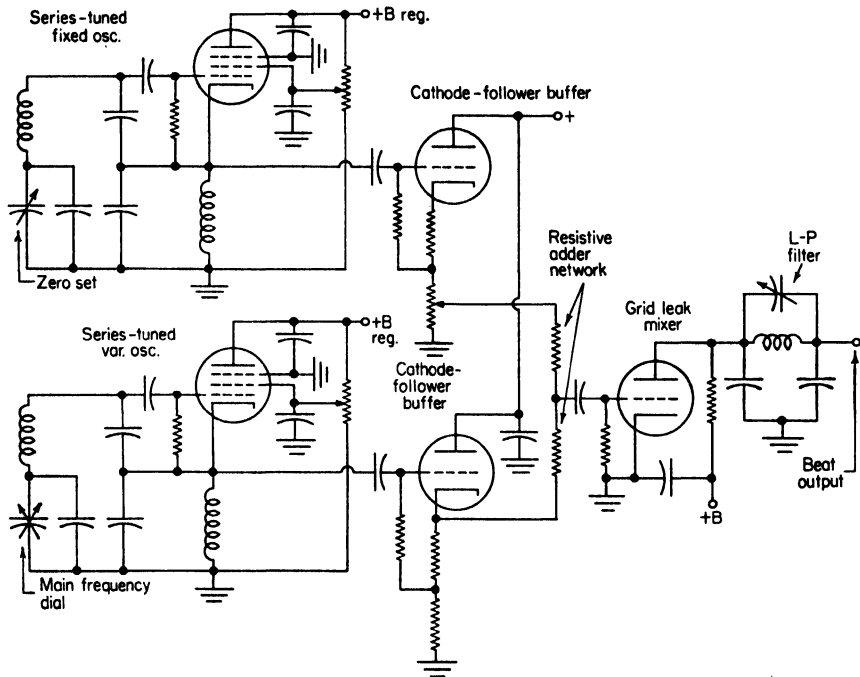
63. Stability. Since both oscillators may be made similar in construction, it is possible to minimize drift with temperature change by obtaining nearly identical frequency-vs.-temperature-time curves for both oscillators. If each oscillator is constructed to be very stable initially, the stability of the beat frequency may be extremely good. The interpolation oscillator manufactured by the General Radio Company (Fig. 91) covers the output-frequency range of 0 to 5,000 cycles with linear dial over


FIG. 91. Simplified schematic of frequency-stable beat oscillator.

the entire range. The maximum drift of the oscillator frequencies in this oscillator is less than 5 cycles from a cold start, and the output frequency will stay within ±0.5 cycle of its set value for hours of operation at room temperature. No temperature control is used. Both fixed and variable oscillators use the series-tuned circuit for maximum stability, the variable oscillator tuning from 42 to 47 kc, and the fixed oscillator being set at 42 or 47 kc by means of a panel switch.

The output-frequency stability of wide-range audio oscillators of the beat-frequency type is hardly less impressive, since it is easy to add negative-temperature-coefficient capacitor compensation to the r-f oscillators. A commercial BFO covering the nominal range from 20 to 20,000 cps shows less than 7 cycles drift of the output frequency in the first hour from a cold start, and generally stays within ±1 cycle of a given setting once it has operated for 1 hr. Compared with the *RC* oscillator which exhibits a stability proportional to frequency, this beat-frequency-oscillator stability is relatively poorer only below 100 cps, approximately equal up to 1,000 cps, and far superior

above 5,000 cps. Furthermore, the provision of zero-setting and cycles-increment adjustments on the BFO enable small frequency changes to be corrected without touching the main dial. Such an adjustment is not readily added to other oscillators.

Beat-frequency oscillators to cover the entire video-frequency spectrum have been constructed, the limiting factor usually being the availability of wide-band low-distortion amplification to follow the mixer. Tuned, tracked amplifier systems may be employed, but their difficulty of adjustment, and the lack of extremely wide-band tuning networks, usually results in the selection of the simpler wide-band amplifiers. The application of distributed amplifiers to this problem may provide even wider-range beat-frequency oscillators than have been employed heretofore.

The range of oscillator frequencies used is very wide. Special low-frequency beat oscillators for frequencies below 100 cps[1] have been made using oscillators below 5,000 cps. Commercially available beat-frequency oscillators using frequencies of 42 to 47 kc, 190 to 230 kc, and 39 to 49 Mc are now in production, and klystron BFOs beating two X-band (10,000-Mc) klystrons are also available commercially. As is apparent from this incomplete listing, the beat-frequency oscillator is a device of great versatility which enjoys wide application.

CHAPTER 17

POWER-SUPPLY SYSTEMS

By Reuben Lee[1]

1. A-c vs. D-c Power Supplies. Vacuum tubes and transistors used in radio transmitters and receivers require power supplies for the various electrodes. A vacuum tube is normally operated with a-c power on the filament, negative d-c voltage or bias on the control grid, and much greater positive d-c voltage on the plate. Screen grids usually operate at positive d-c voltage, and suppressor grids at ground potential. In some industrial applications, unrectified a.c. is applied to the plate, and the rectifying properties of the vacuum tube are used to eliminate the need for a d-c power supply. But for communication purposes, d-c supplies are necessary because a-c supplies cause noise enough to interfere with intelligible transmission and reception.

A transistor usually operates with a small d-c voltage on the emitter or base and somewhat greater d-c voltage on the collector. Current requirements are small. Transistors are well suited to small portable receivers and to other applications in which space, weight, and power consumption must be small.

Because of the universal use of d-c power in the radio field, this chapter primarily deals with d-c power supplies.

2. A-c and D-c Supply Lines. By far the greater number of transmitters and receivers are operated by power taken from public-utility 60-cycle a-c supply lines. The excellent frequency control of large modern power systems, together with the convenience and comparative freedom from power interruption, makes this source of power convenient for communication apparatus. D-c voltages are mostly supplied by rectifiers. Exceptions are bias voltages derived from plate current flowing through cathode resistors (see 3V4 amplifier filament resistor in Fig. 1), or grid current flowing through *RC* networks. These light circuits are best studied in combination with the amplifiers and oscillators of which they are parts. Rectifiers may be of many kinds, and are taken up in Secs. 9 to 21. In those localities where d-c power is used for all other purposes, it becomes necessary that radio equipment, too, operate from the d-c supply lines. Some receivers, such as that shown in Fig. 1, may be operated from an a-c or a d-c supply line or batteries. Tube plate voltage is limited to that of the d-c source. The rectifier is half-wave because there is no transformer. When operating from a d-c line, the rectifier acts simply as a series resistance, but it protects the (usually electrolytic) filter capacitor if the input polarity is wrong. Dynamotors and m-g sets were formerly used for d-c plate voltages in the range of 250 to 600 volts, but they were heavy, expensive, and inflexible with respect to voltage. With the trend toward smaller over-all size and weight, electronic or vibrator devices have largely supplanted rotating machines for d-c source operation.

3. Isolated Power Plants. In districts isolated from utility-system power lines, engine-generator sets are used for electric-power generation. Engines are commonly of the diesel or gasoline types and range in output from 5 to 500 kw. Choice of engine depends on available fuel. If a reciprocating gas engine is used, the user may choose between gasoline and liquefied gas fuels or between air and liquid-cooled engines, according to local conditions. With rapid variations in connected load, both voltage and frequency fluctuations exceed those of a large power network. Ordinary limits for voltage are ±10 per cent, and for frequency ±5 per cent, from nominal

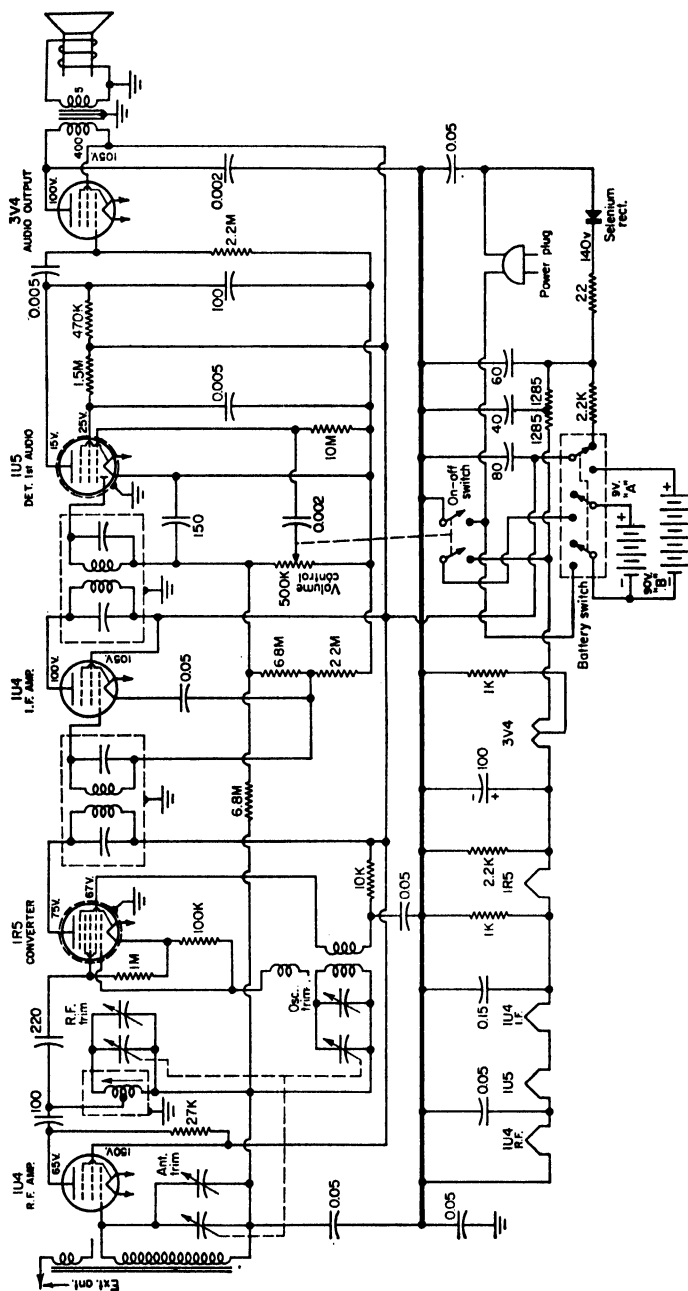
[1] Westinghouse Electric Corp.


FIG. 1. Schematic of Westinghouse H-342P5U receiver showing arrangements for using battery or a-c power.

ratings, even with fast-acting generator-voltage regulators. Satisfactory operation of communication equipment may then require supplementary voltage regulation, several types of which are described in Secs. 35 to 37.

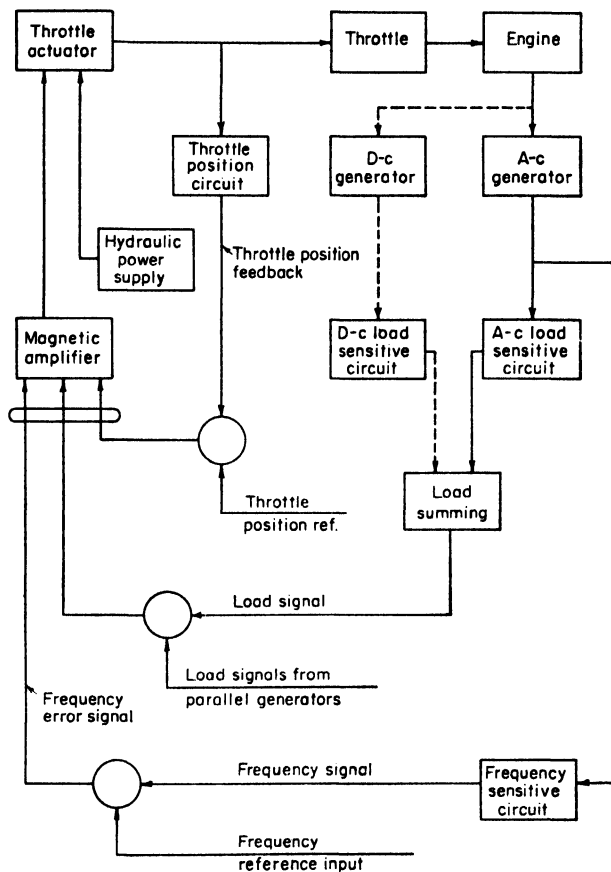
Voltage and frequency fluctuations are mitigated by the use of engine-speed governors. Under steady-state conditions, the usual mechanical governors provide fair speed control and maintain generator voltage within ±2 per cent. But under


FIG. 2. Electric-generator control circuits.

transient load conditions the generator speed may fluctuate widely. For accurate control under these conditions, hydraulic and electric governors have been developed; the electric governor is the faster of the two.

The Westinghouse electric governor is an accurate speed regulator for engine-generator sets. It is applicable to diesel- and gasoline-engine-driven electric-generator sets from approximately 30 kw capacity to the largest sizes, at 50/60 cps or 400 cps.

It senses electrical load change and thereby anticipates speed change. It is therefore faster acting than a mechanical governor which must wait for actual speed change of the driving engine before starting regulator action.

The governor consists of three major component units: an electrical control unit, a throttle actuator, and a hydraulic power supply. The electrical control unit measures generator frequency, generator load, and engine-throttle position. A block diagram is shown in Fig. 2.[1]

The frequency-sensing circuit is a high-gain low-time-delay loop which provides fine speed control under steady-state conditions and fast response under transient conditions. Its primary function is to counteract small frequency shifts at any one load. The load-sensing circuit anticipates the change in prime-mover speed and repositions the throttle to a new load setting before engine speed has materially changed. At the instant of a load change, the throttle-position-indicating circuit receives the error signal from the load-sensing circuit which causes the throttle to be moved to the final throttle position to hold the new load at base frequency The load-sensing, frequency-sensing, and throttle-position-indicating signals feed into a magnetic amplifier totalizer which in turn passes a signal to the control valve of the hydromechanical actuator.

The hydraulic power supply consists of a hydraulic fluid reservoir that houses a hydraulic pump, filter, relief valve, and necessary line connections; the oil reservoir capacity is 1 gal. The pump is driven by a power take-off on the prime-mover engine and absorbs about 1 hp.

If an increased load is suddenly applied to the engine-generator set, the following action results:

1. The wattmeter output for the new load is instantaneously higher than the throttle-position feedback signal for the previous load.

2. This error signal in the load circuit causes the actuator to open the throttle and hold greater load. The actuator begins to move in approximately 0.015 sec and overshoots the correct throttle position for the new load to force the engine, and then returns to the correct position. As the throttle is opened, the throttle feedback signal increases from the previous value and causes the throttle to stop at the new load position where it again nulls the signal in the load potentiometer.

3. As the throttle approaches the new load position and the load signal is nulled, the frequency-sensing circuit makes a final correction and holds the set on frequency at the new steady-state position. The frequency correction comes into play, since with sudden application of load the speed and frequency drop even though the throttle began to move within 0.015 sec of load application. When the frequency drops, the output of the frequency-sensing circuit produces an error signal which causes the throttle to bring the set back on frequency. Performance obtained is as follows:

Steady-state regulation (no load to full load) ± 0.25 per cent
Transient frequency deviation (no load to full load) 1.5 per cent
Transient recovery time (no load to full load) 1 sec

Electric governors provide for automatic load sharing by two or more engine-generator sets so that the difference between a single generator load and its proportional part of the total combined generator load is within 5 per cent of its rated load. This division of load will be accomplished with ±0.25 per cent frequency regulation. Precise regulation is possible because load sharing is accomplished electrically and, therefore, large speed droop is not necessary. The electric governor works on zero per cent speed droop. Speed droop is adjustable from 0 to −5 per cent by manual adjustment where the electric governor operates with droop in parallel with hydraulic governors.

To realize the foregoing performance, engine response must be rapid, and engine-throttle characteristic (horsepower output vs. throttle position) must be very nearly linear.

4. Stand-by Engine Generators. To provide reliable communications at all times regardless of power-source interruptions, transmitting stations are equipped with stand-by engine-generator sets. A stand-by generator must in itself be reliable, else it fails its purpose.

Engine speed, fuel, cooling-system batteries, battery charger, generator, and starter are chosen to meet specified performance at all extremes of ambient temperature,

[1] Westinghouse Descriptive Bulletin 21000.

humidity, altitude, life, load variations, and power factor. Performance specified in EIA Standard RS-173 on Microwave Standby Generators[1] is

Voltage regulation, no load to full load, ±5 per cent over-all
Frequency regulation 20 per cent load to full load, ±1 cycle
Wave shape, within 10 per cent of a sine wave at all points

Full engine speed should be attained within 15 sec after starting, should not vary more than 5 per cent during a load change, and should return to full speed within 8 sec after a load change.

In unattended stations an automatic-transfer panel is provided to switch over to stand-by power whenever the line voltage drops below 98 volts for more than 5 sec. If the stand-by power unit fails, or if line voltage is restored to 104 volts for a period of at least 10 min, the load switches back to the line automatically. Figures 3 and 4 show recommended installation of a stand-by gas engine-generator set.
FIG. 3. Stand-by generator installation.

Maintenance of the stand-by power plant is similar to that familiar to automobile owners, but to provide good reliability it should be scheduled and systematic. The engine should be started periodically. By means of a momentary failure-simulating test switch, the load should be transferred to the engine-driven generator, and meter readings recorded. The load should be left on the generator for a period of 20 min to dry out the lubrication system. At the end of this period, the test switch should be released. Automatic transfer of load back to the power line then takes place.

Battery-charging rate must be adjustable and automatically regulated to replace normal leakage and occasional starting drain. Overcharging may easily occur, with resulting fast disintegration of the positive grids.

5. Battery Operation. Batteries for radio applications are of either the dry or storage type. Dry batteries are used in small portable receivers and instruments. In the design of these devices, precautions should be taken not to shorten the battery life by excessive current drain. Dry-battery shelf life is best at low ambient temperatures. The battery should be replaced before terminal voltage falls to the point at which faulty operation begins. Storage batteries are used in transportation

[1] Electronic Industries Association Standard RS-173, "Emergency Standby Power Generator and Accessories for Microwave Systems." See also Tharp, N. B., Recommendations for Improving Reliability of Standby Engine Generators for Microwave Communications Systems, *Trans. AIEE*, III, 261, April, 1955.

apparatus: automobiles, buses, trucks, airplanes, and trains. Batteries are also used where it is vital that communication and control facilities function without interruption when line power fails. Examples are central power stations and substations. Here the battery voltage is 110 to 125 volts. Care of the batteries is an important part of plant maintenance and should be done in accordance with the battery manufacturer's recommendations. Such is the emphasis on continuity of service that batteries are used at all times, even though station a-c power is available except during very infrequent shutdowns. In power-line carrier telephony, automatic simplex operation requires that the transfer from "send" to "receive" be accomplished in 0.001 sec. This requirement alone eliminates the possibility of switching to any type of stand-by power. Vacuum tubes must operate at the battery voltage, and this restricts the choice of tubes as well as the power output. Such tubes as the 25L6 are extensively used in such service.

Fig. 4. Fuel system for stand-by generator.

6. Vibrators. Vibrators constitute an important means of deriving plate and screen potentials from a storage battery, especially in transportation apparatus. Typical battery voltages are:

6 volts in automobiles
12 volts in buses, trucks, and aircraft
24 volts in aircraft and boats
32 volts in boats, trains, and trolley cars
64 to 110 volts on trains

Vibrators convert these voltages into plate potentials of 250 to 500 volts.

The reliability and performance of vibrators have improved vastly during recent years, especially in the so-called "heavy-duty" size. The vibrator is essentially a vibrating metal reed with a frequency of vibration determined by the mass and stiffness of the reed. Low-power (30-watt) vibrators operate at 115 to 250 cps; heavy-duty (150-watt) vibrators at 60 cps. With good design, the contacts close with very low relative velocity and open with comparatively high velocity. This action eliminates contact bounce, reduces sparking at the "break," and reduces wiping motion and contact erosion. Two principal kinds are used, the self-rectifying and a-c output vibrators. The self-rectifying vibrator with shunt coil is shown in Fig. 5.[1] Current in the coil attracts the reed armature and

Fig. 5. Self-rectifying vibrator with shunt coil.

[1] P. R. Mallory and Co., "Fundamental Principles of Vibrator Power Supply Design," 1947.

starts the vibrations. Current flows first through one half of the primary and then through the other as the vibrator reed switches from left to right contacts. Simultaneously the secondary circuit is open and closed and thus provides d-c output of a voltage determined by the turns ratio of the transformer. A timing capacitor is connected across the transformer primary or secondary to reduce arcing and maintain good wave form.

FIG. 6. Vibrator with separate driver and a-c output.

During the time that the vibrator is accelerating to its normal speed, heavy transient currents flow through the contacts and, unless provisions are made to protect against them, may easily burn up the contacts in a short time. One method of protecting contacts during the starting interval is the so-called "separate driver circuit" of Fig. 6. Here all the power contacts are separated when the reed is at rest but the driver contacts are closed. Power contacts are made of tungsten and driver contacts of precious metal. Because the moving driver contact causes an unbalanced mechanical system careful design is necessary to produce uniform wave shape on both halves of the output wave. Transformer input and output wave forms are shown for correctly adjusted vibrators of the self-rectifying type in Fig. 7, and for the a-c type in Fig. 8. In Fig. 7, separation of contacts starts a transient oscillation as shown by the dotted line. At the end of the contact transfer interval t_2, the other contact closes and damps out the transient. The same thing occurs when the other contacts open and close in the reverse direction during interval t_4. In an a-c vibrator, the contacts reverse during the time when the transient wave crosses the zero axis, thus giving smooth a-c output. A separate rectifier is then used for d-c output.

FIG. 7. Input and output wave forms of self-rectifying vibrator.
FIG. 8. Input and output wave form of a-c vibrator.

It will be noted that the self-rectifying type of vibrator produces d.c. with deep but narrow notches of ripple. This ripple can be smoothed out with a small filter. The effects of contact chatter and bounce, and too much or too little timing capacitance, are shown in Fig. 9.

FIG. 9. Vibrator wave forms with improper conditions.

There is always a small amount of sparking at vibrator contacts. This is a source of radio interference, and the case, shielding, and grounding connections must be arranged carefully, and an r-f filter added to minimize this interference. The audible noise from a vibrator is usually made tolerable by means of cushioning material glued to the inside of the case. The arcing that may occur if one vibrator contact is not making or breaking properly is serious and results in wearing out contacts rapidly. It may be detected by observing the wave shape and may be corrected by contact adjustment.

Arcing of this kind can be detected as a flame in contrast to the tiny sparks of normal operation.

In Fig. 10 the elementary components of a sine-wave a-c 150-watt power supply are shown.[1] Although this circuit shows a vibrator *V* with one power-handling circuit, actually there are four parallel contacts on each side. The vibrator has a separate driving circuit and arc-suppression network made up of C_d and *R*.
FIG. 10. Basic circuit of heavy-duty vibrator.

When rated d-c voltage is applied, with the vibrator at rest, coil current is drawn from the power source through the center reed C_r and the actuating point A_p. This causes the coil to attract the vibrator armature and start the reed vibrating. The nominal frequency is 60 cps. The vibrator is connected through equal and oppositely phased reactor windings *L* to a center-tapped transformer *T*.

Buffer capacitor C_b connected across opposite sides of the vibrator, in conjunction with the reactor *L*, transformer *T*, and tank capacitor C_t, forms a roughly tuned circuit which reverses the direction of current in the transformer primary during the interval when the vibrator center reed swings from one side to the opposite side. This reversal of current prevents heavy arcing at the contacts which would be present if they were required to break the maximum value of direct current which is built up in the primary winding.

Balanced reactor *L* is of a linear type and works in conjunction with the saturated transformer and tank capacitor to produce an essentially sinusoidal output wave. Autotransformer *T* in this simplified circuit has, in addition to its center-tapped primary winding, an extension of sufficient turns to produce the output a-c voltage. Tank capacitor C_t is connected across this extension. On this supply the tank capacitor operates at approximately 330 volts.

Power-point capacitors C_p are connected between the vibrator center reed and the stationary contacts. They are used primarily to maintain stability of operation during the starting interval. Their function is to prevent a flare arc at the contacts when the vibrator is coming up to speed from rest, and while the vibrator frequency is below the resonance frequency of C_b, *T*, and C_t.

When the vibrator approaches the end of useful life, the tungsten material on the contacts of the vibrator is gradually used up. This causes sticking of the contacts, or a flare arc, which causes excessive primary current to be drawn and a circuit breaker to trip. It is then necessary to replace the vibrator. It is usually possible to determine the degree of deterioration of vibrator contacts in advance of actual failure by noting the voltage at any output and comparing it with the proper value for any given condition of input voltage. The gradual loss of tungsten at contacts will cause the time efficiency of the vibrator to be reduced. For a new vibrator, the total on-time interval for each contact is approximately 40 per cent of one cycle. Considering both sides of a set of power contacts, this is an 80 per cent time efficiency. With rated d-c input, this time efficiency will give, say, 300 volts d.c. at full load. When this voltage deteriorates by as much as 15 per cent, the contacts have worn to the point where time efficiency is 69 per cent instead of 80 per cent. When this amount of wear shows up, it is quite likely that at least some of the contacts are approaching a worn-out condition, and it would be well to replace the vibrator. Output voltage in the power supply, under load, can be considered as only an indication of the average condition of the contacts. All contacts are not set exactly the same; hence it is possible for one or more contact pairs to fail even though the average is still acceptable. This condition can be found by inspection.

7. Aircraft Power Supplies. Aircraft electric power is supplied either from storage batteries or from engine-driven generators. In the larger planes, a-c generators are rated up to 60 kva, three-phase, 208 volts, 400 cycles with 120 volts to neutral. Generators driven directly by airplane engines may vary widely in speed and therefore in frequency. Hydraulic transmissions are interposed between alternators and engines to provide constant-speed drives. In airplanes equipped with separate air turbines to drive the generators, the turbines are controlled hydraulically to give constant speed. In both the constant-speed systems, standard variations are ±5 per cent for both voltage and frequency; in other systems these variations may be much wider.

Some electronic equipment requires more precise frequency and voltage regulation. With magnetic amplifier control of the generator voltage regulator and of the transmission-control devices, frequency can be stabilized to 400 cps ±1 cycle, and voltage to 200 ± 5 volts. This has been accomplished with two alternators operating in parallel, and with provision for rapidly switching the load to a ground power unit at times of engine shutdown.[1]

Aircraft-generator wave form varies appreciably between units and from no-load to full-load conditions. This affects d-c power-supply voltage. The 400-cycle supply frequency is subject to random or cyclic low-frequency modulation (2 to 70 cps) which may interfere with amplifier operation and which would require prohibitively large components to be filtered out of the power supply. Performance specifications generally limit this modulation to 2 per cent.

CHARACTERISTICS AND MEASUREMENT OF D.C.

8. Indicating Instruments. Since d.c. is employed largely for radio transmitters and receivers, a brief analysis will be made of its various kinds and their measurement. One reason for this analysis is that instruments of the repulsion-iron or dynamometer type will not read the same as an "average" type on certain kinds of d.c. This difference sometimes causes confusion.

If a d-c ammeter is specified, it usually refers to a D'Arsonval instrument (permanent magnet, moving coil), one that reads "average" values.

Figure 11 shows five typical kinds of d.c., one or more of which are present in any d-c power supply. Steady d.c. is the output from a primary or secondary (storage) battery, or from a suitable filter connected to a pulsating or ripple d-c source. Ripple d.c. is the usual output from a d-c generator, the ripple being a result of commutation. Three types of pulsating d.c. are (1) half-wave rectified single-phase, (2) full-wave rectified single-phase, and (3) three-phase full-wave rectified.

The ambiguity of the term "direct current" is readily apparent when considering Fig. 11, since all these wave forms fall into this classification; *i.e.*, each remains positive. None goes to a negative value. The data on the figure show the minimum voltage as a decimal part of the maximum voltage E_m, *e.g.*, 65 per cent of its maximum, for ripple d.c.

The second column shows the average value of the potential difference as a factor times the maximum E_m. The factor for pulsating d.c. varies from 0.32 for the half-wave rectified single-phase to 0.96 in the case of the full-wave three-phase.

The rms or effective value of a current is such that the heating effect (I^2R) is the same for d.c. or a.c., by definition. For pulsating d.c. the wattage found by multiplying the average voltage by the average current is not the same as the rms voltage times the rms current. The results of these average readings are sometimes called "d-c watts."

The readings of different types of instruments can be predicted from the value of the form factor. On the ripple d.c. from a d-c generator, when the form factor is 1.01 as shown, a D'Arsonval instrument would read 1 per cent lower than would a dynamometer type of instrument. The D'Arsonval instrument reads average, and the dynamometer reads rms. When there is a difference in readings, the rms instru-

[1] Oman, L. R., "An Automatic A-C Generating System for Aircraft," AIEE Paper DP 56-462.

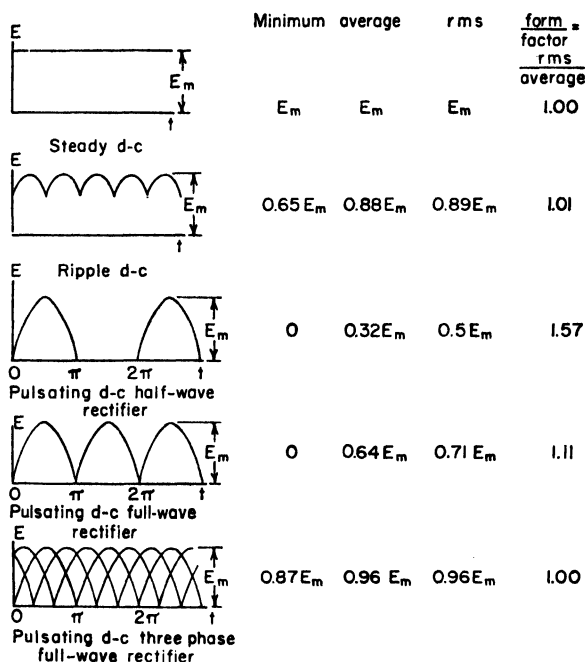
ment always reads higher. For the pulsating d-c output of the single-phase half-wave rectifier, the form factor is 1.57, and an rms instrument (repulsion-iron, dynamometer, or thermocouple) would read 57 per cent higher than the average-reading instrument (D'Arsonval).


Fig. 11. Types and characteristics of d-c power.

Power transformers for radio receivers and amplifiers may be described by specifying d-c volts and d-c amperes output. However, to design a transformer which has rms a.c. flowing in its windings to supply a filter which furnishes average d.c. to the set, the form factor is employed. A full-wave rectifier has the characteristic form factor 1.11, which means that this is the ratio of the rms to average. To supply 100 ma average, the transformer furnishes 111 ma rms (55 ma from each secondary). See Table 1 on page 17-11.
Fig. 12. Characteristics 836 and 5Y3G rectifiers.

RECTIFIER POWER SUPPLIES

9. Rectifier Tubes. Rectifiers are used to convert alternating into direct current. Rectifier tubes or diodes have two electrodes (cathode and anode) and are either high-vacuum or gas-filled. Both kinds are available in a wide range of voltages and currents, from miniature tubes suitable for fractional-watt output to large ones for hundreds of kilowatts. Vacuum rectifiers are characterized by comparatively large internal voltage during conduction known as the "plate characteristic," as shown in Fig. 12. These are for types (1)

5Y3G and (2) 836, with peak inverse voltages of 1,400 and 5,000, respectively. These curves are shown solid up to the average current ratings.

Plate-characteristic voltage divided by plate current gives effective tube resistance at any point. Tube resistance decreases as current increases, up to the emission limit, where all the electrons available from the cathode are used. Filament voltage governs the emission limit and must be closely controlled. If the filament voltage is too high, the tube life is shortened; if too low, the tube will not deliver rated current at the proper voltage.

FIG. 13. Relative dimensions of selenium and silicon rectifiers.

Indirectly heated cathodes have a filament inside a mass of ceramic material coated with the emitting material. These cathodes reduce hum and make quieter operation possible. The thermal time constant of the cathode is approximately 30 sec.

Gas-filled rectifier tubes have an internal voltage drop which is virtually constant and independent of current. Usually this voltage drop is much lower than that of high-vacuum tubes. Consequently, gas-filled tubes are used in high-power rectifiers, where high efficiency and good regulation are important. Gas tubes are limited as to operating frequency. Usually this frequency is below 150 cps but for some (type 866) may be as high as 1,000 cps. These tubes are limited to moderate ambient temperatures (20 to 70°C). Gas-filled tubes also have two current ratings; peak and average. For example, the 872 tube is rated at 5 amp peak and 1.25 amp average plate current. In this tube the internal voltage drop is 10 volts and the peak inverse voltage is 10,000. This is the voltage which occurs in the nonconducting period of the

rectifier. Large gas-filled rectifiers sometimes have tube-filament voltages in quadrature to reduce hum. In high-voltage operation these tubes are subject to occasional arc-back, or conduction in the reverse direction. Rectifier-tube life is increased if cathodes are allowed to reach full operating temperature before plate voltage is applied.

10. Solid-state Rectifiers. Metal-junction rectifiers exhibit greater conduction in the so-called reverse direction, but internal voltage drop is less than in high-vacuum rectifiers. Metal rectifiers are generally smaller but are more limited in temperature and frequency ranges.

Selenium rectifiers are used in both receivers and transmitters. These rectifiers are limited in top operating temperature and for high power are generally air-cooled. Current ratings are increased by means of radiating fins. Unlike vacuum diodes, selenium rectifiers have appreciable reverse current flow, which is a direct loss in efficiency and power output. Usual practice limits the voltage per cell to 35. Internal voltage during conduction is called "forward drop." In humid climates, selenium rectifiers must be protected against penetration of atmospheric moisture to maintain good rectifying properties. In power-supply sizes, operation is limited to frequencies below 2,000 cps.

An improvement over selenium for low and medium power is the silicon diode.[1] This rectifier has small dimensions, will operate at high temperatures and frequencies, and has low forward drop and reverse current. Single diodes have peak inverse voltages up to 1,000. Silicon diodes have the characteristic property that at maximum inverse voltage (Zener voltage) the voltage curve bends abruptly downward with extremely steep slope. Within the limits imposed by reverse current dissipation, this property makes silicon rectifiers useful as voltage regulators. Figure 13 indicates the relative dimensions and properties of selenium and silicon rectifiers. Silicon-rectifier leads should be maintained at the length indicated in Fig. 13 but may be bent to save space. Higher power is obtained by mounting the rectifier on an aluminum plate. Figure 14 shows a silicon cell arranged for plate mounting, and Fig. 15 gives the current ratings for this rectifier with two plate sizes.
FIG. 14. Stud-mounted silicon power rectifier.

Germanium rectifiers are intermediate between selenium and silicon in some respects. Dimensions are approximately the same as the silicon diode of Fig. 13. Forward drop and peak inverse voltage are somewhat lower, and reverse current higher, than in silicon diodes of comparable current rating. The severest limitation is that of operating temperature. Germanium rectifiers are rated for a maximum operating temperature of 65°C. At this temperature, maximum peak inverse voltage and forward current drop to as low as 30 per cent of the 25°C ratings.

Both silicon and germanium diodes are hermetically sealed against ambient moisture and are often mounted on metal plates to increase current ratings. Figure 16 is a curve showing relative performance of selenium, silicon, and germanium rectifiers at 55°C.

11. Thyratrons and Ignitrons. If a grid is placed between anode and cathode in a hot-cathode gas-filled rectifier tube, the tube is called a thyratron. Rectified output may be controlled by means of a-c or d-c voltage applied to thyratron grids. A voltage greater than "critical" must be applied to permit conduction; but after conduction starts, reduction in grid voltage does not affect conduction. This action produces a

[1] James, H. B., "Design and Development of a New Silicon Rectifier Aircraft D-C Power Supply," AIEE Paper DP 56-447. Perlman, Sol, The Power Supply in Military Equipment, *IRE Convention Record*, Part 6, 1956, discusses the advantages in decreased weight, complexity, and heat problems gained from the use of metal-rectifier power-supply systems.
FIG. 15. Silicon power rectifier current ratings—peak inverse voltage 200 volts.
FIG. 16. Comparison of semiconductor rectifiers.

high peak-to-average load-current ratio. Thyratrons are manufactured in most of the gas-filled rectifier-tube sizes, with ratings up to 15,000 volts peak inverse and 6 amp average plate current. They are liable to arc-back under the same conditions as for two-anode gas-filled rectifiers.

For higher output current at power frequencies, ignitrons are used. An ignitron has a cold cathode comprising a pool of mercury. Control is obtained by an ignitor electrode which projects into the mercury pool and which, if supplied with a relatively small electric current, starts the conduction each cycle as desired. The ignitron is

formed chiefly of metal except for the glass insulation which supports the graphite anode in the upper part and the ignitor in the lower end of the tube. The conduction is chiefly by electrons moving from the arc spot on the pool to the anode. The negative electron space charge is neutralized by the formation of positive ions in the mercury vapor, thus allowing the passage of large currents with small potential drop. Use of a metal envelope and water cooling allows high current ratings for relatively small-sized tubes.

Most ignitrons have a water jacket made of stainless steel and provided with spiral baffles built in as a part of the tube. The smallest size is designed to be installed in a clamp which also cools the tube by air or water cooling.

Ignitrons designed for rectifier service are required to operate once each cycle continuously, hence are constructed with baffles within the envelope to shorten the deionization time and thereby minimize the possibility of arc-back. They are provided with two ignitors, one of which is a spare and either of which is suitable for continuous operation on the various circuits used in rectification service, as well as for services where the ignitor is operated by connection to the main anode through a thyratron.

An auxiliary anode, to which the ignitor current is transferred when the tube is fired, is provided to make it possible to prolong the excitation period in circuits where separate ignitor excitation is used. This extension of ignition time is necessary where interphase circuits are used with separate excitation. It is not advisable to operate the separate ignitor-excitation circuits for more than 1 min before starting conduction on the main anode as this may cause mercury to condense on the main anode, increasing the danger of arc-back.

Fig. 17. Dimensions of 5554/679 ignitron.

These tubes must be mounted vertically with the cathode pool down. Operation will be most stable if they are protected from shock and vibration. When the anode of the ignitron is +50 volts or more with respect to the cathode, and a relatively small current is passed through the ignitor into the mercury pool (the ignitor positive with respect to the pool), an arc spot will form on the pool close to the ignitor-mercury junction and conduction to the anode is immediately established.

When ionization occurs the tube will remain conducting until the anode current drops to zero. It is thus necessary to ignite or fire the ignitron in each cycle that operation is desired. Voltage can be applied to the anode simultaneously with its application to the control electrode or ignitor.

After the ignitor has produced the initial arc, no further current need flow through it, and if current is allowed to flow, it will produce overheating of the ignitor. For this reason, circuits should be used which will furnish current to the ignitor in pulses. Firing or ignition of the ignitrons can be accomplished at any point in the a-c cycle by a timing circuit using a thyratron connected between the anode and ignitor of each ignitron. By this means it is possible to control both the number of cycles during which the ignitron operates and the effective current per cycle.

The frequency at which an ignitron operates is limited by the speed of deionization during the half cycle when the tube is not conducting and depends very greatly on the water temperature and anode current. Hence ratings change whenever it is desired to operate the tube at frequencies outside the range of 25 to 60 cycles. The 5554/679 ignitron has dimensions shown in Fig. 17 and 60-cycle ratings of 75 amp average, 600 amp peak, and 4,500 amp surge currents. The peak inverse voltage is 2,100.

FIG. 18. Chart of selection of a particular rectifier for a particular application. (*Amperex Electronics Corp.*)
The ignitor requires 40-amp 100-μsec pulses at 150 positive peak volts; 1.5 gal per min of cooling water is necessary.

12. Rectifier Voltage, Current, and Circuits. Rectifiers are used for d-c power-supply voltages ranging from less than 200 volts in receivers to over 200,000 volts in klystron transmitters. Transmitter plate voltages are often measured in thousands of volts. Danger of electrocution makes advisable the posting of notices such as the following near transmitters.

> H.V. WARNING: Operation of this equipment involves voltages which are dangerous to human life. Operators should observe all safety precautions at all times. Use grounding stick to discharge all high-voltage terminals before servicing. Use one hand only when making internal adjustments.

Current and voltage ratings of power rectifiers are given in the chart of Fig. 18. Rectifier-current values range from a few microamperes in oscilloscope anode d-c supplies to hundreds of amperes in very large transmitters. Generally the rectifying-device average current differs from the total output current of the rectifier circuit. Table 1 gives commonly used rectifier circuits, together with current and voltage relations in the associated transformers. This table is based on the use of a reactor-input filter to reduce ripple. The inductance of the choke is assumed to be great enough to keep the output d.c. constant. With any finite inductance there is always some superposed ripple current which is neglected in the table; this is considered further in Sec. 13.

Single-phase bridge and three-phase full-wave rectifiers require notably low a-c voltage for a given d-c output and low inverse peak voltage on the tubes. The single-phase half-wave rectifier ordinarily has discontinuous output current, and its output voltage is therefore highly dependent upon the inductance of the input filter choke. For this reason, currents and voltages are given for this rectifier in Table 1 without a filter. Unbalanced d.c. in half-wave rectifiers requires the use of larger transformers than in full-wave rectifiers. This is partly overcome in three-phase transformers by the use of zigzag connections. The three-phase full-wave rectifier can be delta-connected on both primary and secondary if desired; the secondary current is multiplied by 0.577 and the secondary voltage by 1.732. Anode windings have more turns of smaller wire in the delta connection.

13. Ripple.[1] Filters used with rectifiers allow the rectified d.c. to pass to the load without appreciable loss, but ripple in the rectified output is attenuated to the point where it is not objectionable. Different types of rectifiers have differing output voltage waves, as indicated in Table 1. Certain assumptions will be made to simplify this discussion:

1. The alternating voltage to be rectified is a sine wave.
2. The rectifying device passes current in one direction but prevents any current flow in the other direction.
3. Transformer and rectifier voltage drops are negligibly small.
4. Filter capacitor and reactor losses are negligible.
FIG. 19. Circuit and wave form of full-wave rectifier.

A single-phase full-wave rectifier is shown in Fig. 19. The alternating components of the output voltage have a fundamental frequency double that of the supply.

[1] Several of the following sections dealing with filtering of power supplies and with small transformer design are largely from Reuben Lee, "Electronic Transformers and Circuits," 2d ed., Wiley, 1955.

Current flow is continuous and E_{dc} has 63.6 per cent of peak amplitude. A full-wave rectifier uses only one-half of the transformer winding at a time; that is, E_{ac} is only half the transformer secondary voltage. A single-phase bridge rectifier (Fig. 20) utilizes the whole of this voltage in producing E_{dc}. The output voltage relations are the same as those of Fig. 19. Although this circuit requires more rectifying tubes, it does not need a transformer midtap.
FIG. 20. Bridge rectifier.

The effect of rectifying more than one phase is to superpose more voltages of the same peak value but in different time relation to each other. Figure 21 gives a comparative picture of the rectified output voltage for three-phase half-wave and full-wave rectifiers. Increasing the number of phases increases the value of E_{dc} and increases the frequency and decreases the amplitude of the alternating components. Ripple frequency is p times that of the unrectified alternating voltage, p being 1, 2, 3, and 6 for the respective waves. Roughly speaking, p may be taken to represent the number of phases, provided that allowance is made for the type of circuit, as in Fig. 22. Rectifiers with $p = 3$ or 6 are derived from three-phase supply lines, and,

FIG. 21. (a) Three-phase half-wave rectifier; (b) three-phase, full-wave or double-Y six-phase rectifiers.

by special connections, rectifiers with $p = 9$, 12, or more are obtained. The frequency of any ripple harmonic is mp, where m is the order of the harmonic.

Ripple voltage for any of these rectifiers can be found from

$$A_n = \frac{2}{T} \int_{-T/2}^{T/2} f(t) \cos n\omega t \, dt \tag{1}$$

where A_n = amplitude of nth ripple harmonic
T = ripple fundamental period
t = time (with peak of rectified wave at $t = 0$)
$\omega = 2\pi/Tp = 2\pi \times$ supply-line frequency
$f(t)$ = ripple as a function of time
$= E_{pk} \cos \omega t, \; T/2 > \omega t > -T/2$

The voltage peak is chosen at $t = 0$ to obtain a symmetrical function $f(t)$ and eliminate a second set of harmonic terms like those in Eq. (1), but with $\sin n\omega t$ under the integral.

Ripple amplitude is given in Fig. 22 for the ripple fundamental and second and third harmonics with reactor-input filters. The ratio P_A of ripple amplitude to direct output voltage is plotted against the number of phases p. Note that P_A diminishes by a considerable amount for the second and third harmonics. In general, if a filter effectively reduces the percentage of fundamental ripple across the load, the harmonics may be considered negligibly small.

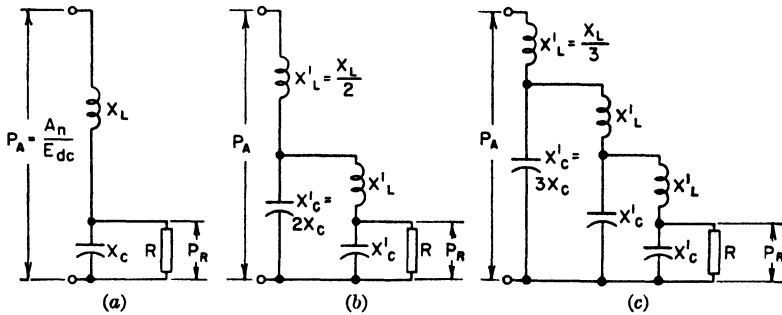
14. Inductor-input Filters. In the inductor-input filter shown in Fig. 23a, the rectifier is a source of nonsinusoidal alternating voltage connected across the filter. For any harmonic, say the nth, the voltage across the whole circuit is the harmonic amplitude A_n, and the voltage across the load is $P_R E_{dc}$, P_R being allowable ripple across the load, expressed as a fraction of the average voltage. Since the load resistance R is high compared with X_C, the two voltages are nearly in phase, and they bear the
FIG. 22. Ripple content of output of various rectifiers.


FIG. 23. Inductor-input filter circuits.

same ratio to each other as their respective reactances, or

$$\frac{P_A}{P_R} = \frac{X_L - X_C}{X_C} = \frac{X_L}{X_C} - 1 \tag{2}$$

From the type of rectifier to be used and the permissible amount of ripple in the load voltage, it is possible to determine the ratio of inductive to capacitive reactance.

When P_R must be kept very small, the single-stage filter of Fig. 23*a* may require the inductor and the capacitor to be abnormally large. It is preferable under this condition to split both the inductor and the capacitor into two separate equal units and connect them like the two-stage filter of Fig. 23*b*. A much smaller total amount of L and C will then be necessary. For this filter

$$\frac{P_A}{P_R} = \left(\frac{X_L' - X_C'}{X_C'}\right)^2 \tag{3}$$

X_L' and X_C' being the reactances of each inductor and capacitor in the circuit. The three-stage filter of Fig. 23*c* may be more practicable for still smaller values of P_R. Here

$$\frac{P_A}{P_R} = \left(\frac{X_L' - X_C'}{X_C'}\right)^3 \tag{4}$$

and, in general, for an n-stage filter,

$$\frac{P_A}{P_R} = \left(\frac{X_L' - X_C'}{X_C'}\right)^n \tag{5}$$

It is advantageous to use more than one stage only if the ratio P_A/P_R is high. The gain from multistage filters is realized only for certain values of P_A/P_R as shown by Fig. 24. The increase in P_A/P_R gained by splitting up the same amount of L and C into two or three stages is indicated in Fig. 24, the inductor and capacitor having the same "lumped" values. The attenuation in multistaging is enormous for high X_L/X_C. For lower ratios there may be a loss instead of a gain, as shown by the intersection of the two upper curves.

FIG. 24. Ripple attenuation as a function of filter and ratio of filter reactances.

Other factors may influence the number of filter stages. In some applications modulation or keying may require that a definite size of filter capacitor be used across the load. Usually these conditions result in a single-stage filter, where otherwise more stages might be most economical.

Table 1 shows filter reactors in the negative lead, which may be at either ground or high potential. If low ripple is required in the filtered output, it is usually preferable to locate the filter reactors in the high-voltage lead. Otherwise, there is a ripple-current path through the anode transformer winding capacitance to ground which by-passes the filter reactor. Ripple then has a residual value which cannot be reduced by additional filtering. In a three-phase zigzag full-wave circuit, with center tap used for half-voltage output, separate reactors should be used in the positive leads; placing a common reactor in the negative lead introduces high-amplitude ripple in the high-voltage output.

In rectifiers with low ripple requirements, both filament and anode windings should be accurately center-tapped to avoid low-frequency ripple, which is difficult to filter. Three-phase leg voltages should be balanced for the same reason.

Sometimes an inductor-input filter is tuned as in Fig. 25. The addition of C_1 increases the effective reactance of the inductor to the fundamental ripple frequency. Both regulation and ripple of this type of filter are improved. The filter is not tuned for the ripple harmonics, so the use of high-Q filter inductors is unnecessary. An increase in effectiveness of the filter inductor of about 3:1 can be realized in a single-phase full-wave rectifier circuit. Tuned filters are less effective with three-phase
Fig. 25. Shunt-tuned filter.
Fig. 26. Series-tuned filter.

rectifiers because slight phase unbalance introduces low-frequency ripple which the filter does not attenuate.

Filters may be tuned as in Fig. 26, where C_1 is connected to a tap near the right end of L, and C_2 is chosen to give series resonance and hence zero reactance across the load at the fundamental ripple frequency. Because of choke losses, the impedance across R_L is not zero, but the resulting ripple across R_L can be made lower than without the use of C_1. Ripple is attenuated more than in the usual inductor-input filter, but regulation is not substantially different.

Where current is small, so that E_{dc} is not unduly affected, filter inductors are often replaced by resistors. This practice is often found in receivers. Plate current for all tubes flows through the first filter-stage inductor. But current for the r-f amplifiers is usually small and flows through resistors in successive filter stages. Such a filter is said to be graded.

15. Capacitor-input Filters.[1] When the filter has no inductor between rectifier and first capacitor, rectifier current is not continuous throughout each cycle and the rectified wave form changes. During the voltage peaks of each cycle, the capacitor charges and draws current from the rectifier. During the rest of the time, no current is drawn from the rectifier, and the capacitor discharges into the load.

Comparison between the rectified voltage of inductor input and capacitor-input filters in a single-phase full-wave rectifier may be seen in Fig. 27. The two tube currents I_1 and I_2 in *a* add to a constant d-c output, whereas in *b* the high-peaked tube currents flow only while the rectified voltage is higher than the average d-c voltage. *Average* current per tube in both cases is half the rectifier output. With large values of capacitance, the rectified voltage in Fig. 27*b* increases to within a few per cent of the peak voltage. Ripple, average rectified voltage output, and rectifier current are dependent on the capacitance, the supply-line frequency, and the load resistance. They are dependent also on rectifier internal resistance because it affects

[1] Waidelich, D. L., Diode Rectifying Circuits with Capacitance Filters, *Trans. AIEE*, **61**, 1161, December, 1941.

the peak value of current which the filter capacitor can draw during the charging interval Δt.

In Figs. 28, 29, and 30, R_S is the rectifier series resistance, including the transformer resistance. Results accurate to within 5 per cent are obtained if the rectifier resistance corresponding to peak current $\hat{I}_P$ is used in finding R_S. The process is cut-and-try, because $\hat{I}_P$ depends on R_S, and vice versa, but two trials usually suffice. Three-phase rectifiers are rarely capacitor-input. The figures are from Lee, *op. cit.*
Fig. 27. Voltage and current comparisons in (*a*) reactor-input and (*b*) capacitor-input circuits.
Fig. 28. D-c voltage in half-wave rectifier with capacitor-input filter.

In Fig. 30 the peak current indicates whether the peak current of a given tube is exceeded, and the rms current determines the transformer secondary heating. The v-a ratings are greater, but *ratios* of primary to secondary v-a ratings given in Table 1 hold for capacitor-input transformers also.

One of the assumptions implied at the beginning of Sec. 15, namely, that transformer and rectifier voltage drops are negligibly small, cannot usually be made when capacitor-input filters are used, because of the large peak currents drawn by the capacitor during the charging interval. Such charging currents drawn through finite resistances affect both the d-c output voltage and the ripple in a complicated manner, and simple analysis such as that given for inductor-input filters is no longer possible. Figure 31
FIG. 29. D-c voltage in full-wave rectifier with capacitor-input filter.
FIG. 30. Peak, average, and rms rectifier current with capacitor-input filter.

is a plot of the ripple in the load of capacitor-input filters with various ratios of source to load resistance, and for three types of single-phase rectifiers. These curves are useful also when resistance is used in place of an inductor at the input of a filter. ω is 2π times the a-c supply frequency, R_L is the load resistance, and R_S the source resistance.
FIG. 31. Rms ripple voltage of capacitor-input filters.
FIG. 32. D-c voltage in full-wave voltage doubler.

When LC filter stages follow a capacitor-input filter, the ripple of the latter is reduced as in Fig. 24, except that the value of P_A must be taken from Fig. 31. When an RC filter stage follows any type of filter, the ripple is reduced in the ratio R/X_c represented by the RC stage.

16. Voltage Multipliers.[1] To obtain more d-c output voltage, the circuit of Fig. 32 is often used. With proper values of circuit elements the output is nearly double the a-c peak voltage. Tube inverse peak voltage is little more than the d-c output voltage, and no d-c unbalance exists in the anode transformer. Current output available from this circuit is less than from the single-phase full-wave circuit for a given rectifier tube. Current relations are given in Fig. 30. The circuit of Fig. 32 is that of a
Fig. 33. D-c voltage in half-wave voltage doubler.

full-wave *voltage doubler*. A circuit used in transformerless receivers is the half-wave voltage doubler shown in Fig. 33, together with curves of d-c voltage. Peak currents for this circuit are somewhat less than those of Fig. 30.

Voltage tripling and quadrupling circuits also are used, either to increase the d-c voltage or to avoid the use of a transformer. Such circuits are those of Fig. 34. At $\omega CR_c = 800$, in Fig. 34a[1] E_{dc} is nearly three times and in b nearly four times the peak a-c supply voltage; peak inverse voltage is nearly double the peak supply voltage in both these circuits; ripple is 0.1 per cent in the tripler and 0.3 per cent in the quadrupler; peak current in the tripler is 400 times average, and in the quadrupler 100 times average (see Chap. 15, Sec. 43).

17. Oscilloscope High-voltage Power Supplies. In cathode-ray tubes for oscilloscopes or television receivers, high-voltage low-current sources of d-c power are needed for the accelerating anodes. Voltages range from 1 to 30 kv, and currents are on the order of 1 ma down to 1 μa.

[1] Waidelich, D. L., and H. A. Taskin, Analyses of Voltage Tripling and Quadrupling Circuits, *Proc. IRE*, **33**, 449, July, 1945.

Because of the many turns of wire required in high-voltage 60-cycle transformers, high-frequency power supplies are often used.[1] A tetrode or pentode tube is used in a single- or double-tuned oscillator circuit, with a stepup transformer. The secondary load may be a voltage doubler, tripler, or quadrupler, depending on the voltage needed from the oscillator. Frequencies used in such power supplies range from audio to medium high radio frequency. The oscillator is usually operated class B or C; loaded
FIG. 34. (a) Voltage-tripling and (b) voltage-quadrupling circuits.

Q ranges from 10 to 20. Lower values of Q result in oscillator instability with load changes.

In television receivers, high voltage is derived from the horizontal deflection circuit, which operates at 15,750 cps. A winding extension on the horizontal output transformer is connected to the half-wave rectifier which supplies high voltage to the cathode-ray tube.

A third alternative is the switching transistor inverter shown in Fig. 35.[2] Here the frequency is fixed by volt-seconds storage in a grain-oriented nickel-steel core. A part of the d-c supply voltage is applied across one half primary which induces base drives of polarity to make the better-conducting transistor conduct still better and make the other transistor a better insulator. This process is regenerative and in a very short time one transistor is driven to saturation while the other transistor is driven to cutoff. Full d-c supply voltage less the small saturated emitter-collector voltage drop is applied across one half primary which induces a voltage constant with time until the core saturates. At this time there is no longer sufficient change in core flux to induce a voltage; so the base drives disappear. The core flux returns from its peak saturated value along a slight slope to its remanent value. This slope starts a voltage reversal which quickly builds up in the opposite direction. Square-wave output of 1,000 to 10,000 cps is produced, the frequency depending on the core material and core area. Toroidal cores are used. Insulation of the high-voltage winding is more difficult than with the usual transformer construction.

FIG. 35. Switching transistor high-voltage supply.

18. Rectifier Regulation. The no-load to full-load voltage regulation[1] of a rectifier comprises three distinct components:

1. The d-c resistance or IR drop
2. The commutation reactance or IX drop
3. The capacitor charging effect

The first component can be reduced to a small value by the use of tubes, transformers, and inductors having low resistance. Mercury-vapor tubes are useful in this respect, as the internal voltage drop is low and almost independent of load-current variations.

Commutation reactance can be kept low by proper transformer design, particularly where the ratio of short-circuit current to normal load is high.

During part of each cycle, both tubes of a single-phase full-wave rectifier are conducting. During this interval one tube loses its current and the other one builds up to normal current. Because of the inevitable reactance in the transformer, this change does not take place immediately. Short-circuit current is initiated which prevents the rectified voltage wave from retaining its normal shape, so that for a portion of each cycle the rectified output is zero.

In a single-phase rectifier, the *average* voltage cut out of the rectified voltage wave by commutation is

$$V_{av} = I_{dc}X/2\pi \tag{6}$$

Commutation reactance drop for polyphase rectifiers is

$$pI_{dc}X'/2\pi \tag{7}$$

where X' = transformer leakage reactance from line to neutral on the secondary side, and p = the number of phases in Fig. 22.

When high winding resistance limits short-circuit current, commutation has less effect than Eq. (6) would indicate. This condition prevails in small rectifiers; the IX drop is negligibly small because of the small transformer dimensions.

In large rectifiers, all rectifier components have low losses to prevent power wastage or overheating, and the IR drop is a very small percentage of the total. At the same time, a large transformer requires careful design to keep the IX drop reasonably small. Therefore, in large rectifiers the IX drop is the dominant cause of regulation. An example with 60 kva rating has 0.7 per cent IR drop and 6 per cent IX drop.

In medium-sized rectifiers the IR and IX drops may be equal, or at least comparable in value. In such rectifiers these two components of regulation do not add arithmetically. Commutation interval θ depends on the short-circuited reactance when resistance is negligible, but if resistance is appreciable θ is related to the ratio X/R exponentially.[2] The increase in regulation caused by commutation reactance may be found from Fig. 36, in terms of d-c output voltage E_{dc}. In this figure the regulation of three widely used rectifiers (single-phase full-wave, three-phase half-wave, and three-phase full-wave) is given
Fig. 36. Increase in rectifier regulation due to transformer reactance.

[1] The term "regulation" is taken to be the loss in voltage within the device divided by the voltage at the output terminals when drawing a given current. Thus

$$\text{Voltage regulation} = \frac{E_{\text{no load}} - E_{\text{specified load}}}{E_{\text{specified load}}}$$

[2] Prince, D. C., and P. B. Vogdes, "Mercury Arc Rectifiers and Their Circuits," p. 216, McGraw-Hill, 1927. See also *Tele-Tech and Electronic Industries*, October, 1953.

in a manner which enables one to proceed directly from the IR component of regulation to total regulation.

X and R are ohms per phase except that X/R ratio is for the whole secondary in single-phase full-wave rectifiers. R in X/R ratio includes primary R in all cases. R in $I_{dc}R/E_{dc}$ is for two windings in three-phase full-wave rectifiers. To obtain total regulation, project $I_{dc}R/E_{dc}$ vertically to one-phase or three-phase line. Project this point to the left to proper X/R line. Abscissa at left gives total regulation. An example is indicated by the dotted line. In this example, the rectifier is three-phase full-wave.

$$E_{dc} = 2{,}000 \text{ volts} \qquad \frac{X}{R} = 2$$

$$I_{dc} = 1 \text{ amp}$$

$$R = 60 \text{ ohms} \qquad \frac{I_{dc}R}{E_{dc}} = \frac{60}{2{,}000} = 3 \text{ per cent}$$

$$X = 120 \text{ ohms}$$

Total regulation = 1.68 × 3 = 5.04 per cent.

If the rectifier had no filter capacitor, the rectifier would deliver the average value of the rectified voltage wave, less regulation components 1 and 2. But with a filter capacitor, there is a tendency at light loads for the capacitor to charge up to the peak value of the rectified wave. At zero load, this amounts to 1.57 times the average value, or a possible regulation of 57 per cent in addition to the IR and IX components, for single-phase full-wave rectifiers. This effect is smaller in magnitude for polyphase rectifiers, although it is present in all rectifiers to some extent.

Suppose that the rectifier circuit shown in Fig. 19*a* delivers single-phase full-wave rectifier output as shown in Fig. 19*b* to an inductor-input filter and thence to a variable load. In such a circuit, the filter inductor keeps the capacitor from charging to a value greater than the average E_{dc} of the rectified voltage wave at heavy loads. At light loads the d-c output voltage rises above the average of the rectified wave, as shown by the typical regulation curve of Fig. 37.
FIG. 37. Rectifier regulation curve.

Starting at zero load, the d-c output voltage E_0 is 1.57 times the average of the rectified wave. As the load increases, the output voltage falls rapidly to E_1 as I_1 is reached. For any load greater than I_1, the regulation is composed of only the two components IR and IX. It is good practice to use a bleeder load I_1 so that the rectifier operates between I_1 and I_2.

Filter elements X_L and X_C determine the load I_1 below which voltage rises rapidly. The filter, if it is effective, attenuates the a-c ripple voltage so that across the load there exists a d-c voltage with a small ripple voltage superposed. A choke-input filter attenuates the harmonic voltages much more than the fundamental, and, since the harmonics are smaller to begin with, the main function of the filter is to take out the fundamental ripple voltage. This has a peak value, according to Fig. 22, of 66.7 per cent of the average rectified d-c voltage for a single-phase full-wave rectifier. Since this ripple is purely a.c. it encounters a-c impedances in its circuit. If we designate the choke impedance as X_L and the capacitor impedance as X_C, both at the fundamental ripple frequency, the impedance to the fundamental component is $X_L - X_C$, the load resistance being negligibly high compared with X_C in an effective filter. The d-c voltage, on the other hand, produces a current limited mainly by the load resistance, provided that the choke IR drop is small.

To prevent capacitor effect the choke must be large enough so that I_{ac} is equal to or less than the bleeder current I_1. This consideration leads directly to the value of choke inductance. The bleeder current I_1 is E_1/R_1, where R_1 is the value of bleeder resistance. The ripple current is the fundamental ripple voltage divided by the ripple circuit impedance.

$$I_{ac} = \frac{0.667E_1}{X_L - X_C}$$

Equating I_1 and I_{ac}, for a single-phase full-wave rectifier

$$R_1 = \frac{X_L - X_C}{0.667} \tag{8}$$

Thus, the value of capacitance also has an effect, but it is minor relative to that of the choke. In a well-designed filter, the choke reactance X_L is high compared with X_C. Therefore, the predominant element in fixing the value of R_1 (and of I_1) is the filter reactor.

Polyphase rectifiers have similar effects, but the rise in voltage is not so great because of the smaller difference between peak and average d-c output. The bleeder resistance for eliminating capacitor effect can be found in general from

$$R_1 = \frac{X_L - X_C}{P_1} \tag{9}$$

where P_1 is the fundamental ripple peak amplitude from Fig. 22, and X_L and X_C are the filter reactances at fundamental ripple frequency.

FIG. 38. Voltage rise in single-phase full-wave rectifier at light loads.

Between load I_1 and zero load, the rate of voltage rise depends upon the filter. Figure 38 shows the voltage rise as a function of the ratio $(X_L - X_C)/R_L$ for a single-phase full-wave rectifier with $IR + IX$ regulation of 5 per cent. Reactances X_L and X_C are computed for the fundamental ripple frequency.

Capacitor-input filters have the voltage-regulation curves shown in Figs. 28, 29, and 32 for their respective circuits. At light loads these filters may give reasonably good regulation, but it is possible to get very poor regulation at heavier loads.

19. Rectifier Transients. Transients which occur when power is first applied are spasmodic. Power may be applied at any instant of a-c voltage cycle, and the suddenly impressed rectifier voltage ranges from zero to E_{pk}. Starting transients are difficult to observe on an oscilloscope because of their random character. It is necessary to start the rectifier several times for one observation of maximum amplitude, and the trace is faint because it appears for a very brief time.

Excessive current inrush, which occurs when a power transformer is connected to a supply line, plagues rectifier design. The phenomenon is associated with core saturation. Heavy initial magnetizing current is drawn from the line, limited only by primary winding resistance and leakage inductance. This heavy current has a peaked wave form which may induce momentary high voltages by internal resonance in the secondary coils and damage the rectifier tubes. Or it may trip a-c overload relays. The problem is especially acute in large transformers with low regulation. A common remedy is to start the rectifier with external resistors in the primary circuit and short-circuit them a few cycles later. Some rectifiers are equipped with voltage regulators which reduce the primary voltage to a low value before restarting.

In some applications the load is varied or removed periodically. Examples of this are keyed or modulated amplifiers. Transients occur when the load is applied (key down) or removed (key up), causing, respectively, a momentary dip or rise in plate voltage. If the load is a device which transmits intelligence, the variation in filter output voltage produced by these transients results in the following undesirable effects:

1. Modulation of the transmitted signal
2. Frequency variation in oscillators, if they are connected to the same plate supply
3. Greater tendency for key clicks, especially if the transient initial dip is sharp
4. Loss of signal power

Although the tendency for key clicks in the signal may be reduced by attention to the d-c-supply filter elements, the clicks may not be entirely eliminated. Where key-click elimination is necessary, some sort of key-click filter is used.

In a choke-input filter, voltage surges are developed across the choke under the following conditions:

1. *Ripple Voltage.* With large rectifier commutation angles, or with grid-controlled rectifiers, a surge occurs once each ripple cycle. In the limit, this surge equals the rectifier peak voltage.

2. *Initial Starting Surge.* This surge adds to output d-c voltage. Under the worst conditions it raises the voltage at this point to twice normal and occurs every time rectifier plate voltage is applied.

3. *Keying or Modulation Transient.* Surge value depends upon L, C, and R_L, and is limited by wave-shape considerations. This occurs each time the key is opened or closed, or load is varied.

4. *Short-circuit Surge.* If R_L is suddenly short-circuited, full d-c voltage appears across the filter reactor until the circuit breaker opens. This occurs occasionally. Rectifiers are sometimes arranged so that, if the short circuit persists, the circuit breaker recloses three times and then remains open.

5. *Interruption of Reactor Current.* This surge voltage is limited only by losses and capacitance of the circuit, and it may be large. Unless the reactor is designed to produce this voltage, it occurs only through accident.

Conceivably, surges 1, 2, and 3 may occur simultaneously and add arithmetically. A reactor insulated to withstand surges 1 plus 2 plus 3 also would withstand surge 4. A reasonable value of peak surge voltage comprising these factors is $2\frac{1}{2}$ times the full d-c working voltage. If surges 1 and 5 are too much for reasonable insulation, the reactor is protected by a gap or other means.

If a rectifier is disconnected from the supply line while the load is off, interruption of plate transformer peak magnetizing current may cause high voltages to appear at random in the windings in much the same way as reactor current interruption causes high voltages. This is especially true if the transformer operates at high core induction. The effect is partly mitigated by the arc energy incident to the opening of the disconnecting switch. But unless the plate transformer is insulated specifically to prevent dangerously high voltages, protective elements may have to be added.

Insufficient attention sometimes is given to the manner in which power-supply lines are brought into buildings. This is particularly important where a rectifier is supplied by overhead high-voltage lines. Because of their relatively high surge impedance, lightning and switching surges occurring on such lines may cause abnormally high voltages in a rectifier and break down the insulation of transformers or other component parts. The likelihood of such surges occurring should be taken into account before the transformers are designed.

Underground-cable power lines impose much less severe hazards because they are protected from lightning strokes, and because they have about one-tenth the impedance of overhead lines. Surges on these cables have much lower values compared with those on overhead lines carrying the same rated voltage. Protection against these surges varies with the type of installation.

The best protection is provided by an indoor power system with an underground cable connecting it to the rectifier. Good protection is afforded by oil-insulated outdoor surgeproof distribution transformers, stepping down to the rectifier a-c power-supply voltage, with an underground cable between the distribution transformer and rectifier. No protection is provided when overhead lines come directly into the rectifier building.

With the trend to dry-type insulation, it is desirable to use lightning arresters on overhead lines where they enter the building. Because of their low impulse ratio, dry-type transformers require additional arresters inside the building. When a line surge is discharged by a lightning arrester, there is no power interruption.

20. Rectifier Filter Charts. Various properties of filters, such as ripple, regulation, and transients, may impose conflicting conditions on rectifier design. To save time in

what otherwise would be a laborious cut-and-try process, charts are used. In Fig. 39 the more usual filter properties are presented on a single chart to assist in arriving at the best filter directly. This chart primarily satisfies ripple and regulation Eqs. (2) and (9) for a choke input filter.[1]

Rectifier connection	50	60	400
3φ half wave	31	37.5	250
3φ full wave	62.5	75	500
Fig. 39. Choke-input filter chart.

Abscissa values of the right-hand scale are bleeder conductance in milliamperes per volt, and of the left-hand scale, filter capacitance in microfarads. Ordinates of the lower vertical scale are inductance in henrys. Lines representing various amounts of ripple in the load are plotted in quadrant I, labeled in both decibels and rms per cent ripple. In quadrant II, lines are drawn representing different types of rectifiers and supply-line frequencies. A similar set of lines is shown in quadrant IV.

Two orthogonal sets of lines are drawn in quadrant III. Those sloping downward to the right represent resonant frequency of the filter L and C, and also load resistance R_L. The other set of lines is labeled $\sqrt{L/C}$, which may be regarded as the filter impedance. The transient properties of the filter are dependent upon the ratio of $\sqrt{L/C}$ to R_L.

[1] Lee, Reuben, Choke Input Filter Chart, *Electronics*, September, 1949, p. 112.

The L scale requires a correction to compensate for the fact that ripple is not exactly a linear function of L but rather of $X_L - X_C$. The curves in the lower part of quadrant IV give the amount of correction to be added when the correction is greater than 1 per cent.

The following instructions apply for using the chart.

1. Assume suitable value of bleeder resistance or bleeder current I_1 in milliamperes per volt of E_{dc}. This is also steady-state peak ripple current in milliamperes.
2. Trace upward on assumed bleeder ordinate to intersect desired value of load ripple, and from here trace horizontally to the left to diagonal line for rectifier and supply frequency used. Directly under, read value of C.
3. Trace downward on same assumed bleeder ordinate to intersect diagonal line below for rectifier and supply frequency, and read value of L.
4. From desired ripple value, determine correction for L on graph at lower right, and add indicated correction to value of L.
5. Using corrected value of L and next standard value of C, find intersection in quadrant III, and read maximum resonant frequency f_r.
6. Using same values of L and C as in 5, read value of ratio $\sqrt{L/C}$.
7. Under intersection of $\sqrt{L/C}$ with load resistance R_L read values of the four transients illustrated in Fig. 40 (in per cent).

Transient conditions when rectifier is started

Transient conditions with variable load
FIG. 40. Four transient conditions in choke-input filter circuit and curves.

Example (shown dashed): Three-phase full-wave 60-cycle rectifier; E_{dc} = 3,000 volts I_2 = 1 amp; I_1 = 96 ma; load ripple = −50 db; balanced line.

Solution:

Bleeder ma/volt = 0.032
C = 4.5 μf (use 5 μf)
Scale value of L = 0.78 henry; corrected value = 0.82 henry
Resonant frequency = 75 cps
Load resistance R_L = 3,000 ohms
$i_m = 7I_2$ = 7 amp; ΔE_D = 12 per cent; ΔE_R = 15 per cent; ΔE_s = 80 per cent

In polyphase rectifiers the possibility exists of enough phase unbalance to impress a voltage on the filter having a frequency lower than the normal fundamental ripple frequency. If the filter L and C resonate near the unbalance frequency, then excessive ripple may be expected. L and C should have a resonant frequency lower than the unbalance frequency to avoid this trouble. Quadrant III of the chart has a series of lines labeled f_r, and the intersection of L and C thereon indicates this resonant frequency. It should be no higher than the value given in the small table on the chart if excessive ripple is to be avoided. This table is based on 2 per cent maximum unbalance in the phase voltages.

For most practical rectifier filters, transient conditions fall within the left-hand portion of the third quadrant. The other conditions sometimes help in the solution of problems in which L and C are incidental, *e.g.*, the leakage inductance and distributed capacitance of a plate transformer.

Although the chart (Fig. 39) applies directly to single-stage untuned filters with constant choke inductance, it can be used for other types with modifications:

1. *Shunt-tuned Choke per Fig. 25.* Figure 39 can be used directly for C, but, for a given amount of ripple, divide the chart values of L by 3 to obtain the actual henrys needed in the choke.
2. *Swinging Choke.* If at light load the filter choke swings to S times the full-load value of henrys, multiply the capacitance obtained from the chart by the ratio S to find the capacitance needed (C_n). The value of L obtained by projecting the bleeder current downward is the maximum or swinging value. It must be divided by S to obtain the full-load value. Transient conditions then may be approximated by using C_n and the full-load value of henrys.
3. *Two-stage Filters.* In a filter with two identical stages, the chart can be used if it is recognized that the ripple is that on the load side of the first choke. For example, if the filter consists of two stages both equal to that in the example given for the single-stage filter, the ripple would not be -100 db but -75 db, because of the fact that the rectifier output has (per Table 1) only 4 per cent ripple, which is -25 db.

The regulation in a two-stage filter, as far as capacitor effect is concerned, depends upon the inductance of the first choke as in the single-stage filter. Therefore the chart applies directly to the inductance and capacitance of one stage. The peak ripple current likewise depends upon the inductance of the first choke, regardless of the location of the bleeder resistor. Transients, however, are more complicated, owing to the fact that the two stages interact under transient conditions.

21. Rectifier Tests. Even though the transformers, chokes, tubes, and capacitors have been tested before assembly of the rectifier, performance tests of the rectifier are desirable. These generally include tests of output, regulation, efficiency, ripple, and input kilovolt-amperes or power factor. Accurate meters should be used, and polyphase rectifiers should have balanced supply voltages. Wiring is tested at some voltage higher than normal, preferably with transformers, tubes, and capacitors disconnected to avoid damage during the test. Ordinary care in testing is sufficient except for regulation tests. If the regulation is low, the difference in meter readings at no load and full load may be inaccurate. Differential measurements are more accurate, such as a voltmeter connected between the rectifier and a fixed source of the same polarity and voltage. Artificial loading of a high-voltage rectifier is often a problem. Water rheostats have been used for this purpose. Load tests, preferably in combination with the transmitter or other apparatus which the rectifier is to supply, are safeguards against field troubles. Operating tests are essential when the load is keyed or modulated, so that overheating or inadequate transformer operation may be detected.

Ripple is measured either with a special hum-measuring instrument or with an RC network arranged to block the d.c. from the measuring circuit. C and R values in the measuring circuit should be so chosen as to avoid influencing the ripple or loading the rectifier transformer. Sometimes capacitance dividers are used for this purpose. The problem of proper values becomes particularly critical with high-voltage low-current rectifiers. The effect of stray capacitance is especially important.

POWER-SUPPLY TRANSFORMERS

22. Construction. Most electronic transformers are small, and for small transformers the shell-type core is usually most suitable because only one coil is required. The magnetic path is divided, half the flux enclosing one side of the coil and half the other. The coil opening is called the window. Between the windows is the core tongue, which is twice as wide as the iron around the rest of the window. The core is built up of thin laminations to reduce eddy-current losses; typical shapes are shown
FIG. 41. Shell-type laminations.

in Fig. 41. Alternate stacking of the lamination pairs may be used to reduce magnetic reluctance and keep magnetizing current small. To reduce assembly cost, this alter-
FIG. 42. Core-type laminations.
FIG. 43. Type C core.

nate stacking is sometimes done in groups of two or more laminations, with some increase in magnetizing current. A wide range of sizes of shell-type laminations is available. At 60 cycles, common thicknesses are 0.014 in., 0.019 in., and 0.025 in.

Shell-type laminations are made with proportions to suit the transformer. In the E-I shape a scrapless lamination is widely used. Two Es facing each other are first punched, and the punched-out strips are of the right dimensions to form two Is. Then the Es are cut apart. This economy of material is not justified in transformers in which turns per layer, and hence window width, must be reduced relative to window height.

For some applications, the core-type transformer is preferable. In these there is only one magnetic path, but there are two coils, one on each leg of the core. Some core-type laminations are shown in Fig. 42.

Cores wound from continuous steel strip are widely used. One common shape is illustrated in Fig. 43; it is known as the type C core. Steel strip is first wound to the proper build-up on a mandrel. The wound core is then annealed, impregnated with a bond, and cut in two to permit assembly with the coil. After assembly with the coil, the core is held together with a steel band. Several advantages accrue from this construction, which will be discussed in Sec. 23.
FIG. 44. Single type C core and coil assembly.

Assemblies using two type C cores correspond to shell-type laminations. Because it is simpler to assemble a single-core loop, a single core is often used, especially in

small sizes (see Fig. 44). In 60-cycle service core laminations are usually stacked alternately to produce an overlapping joint. This is approximated in type C cores with ground gap surfaces which fit closely together. Either type of core can be used with core gaps; laminations are stacked butting, with no overlap. The desired amount of gap material, such as fishpaper, is inserted between the gap surfaces.

A shell-type transformer with punched laminations is shown in Fig. 45.

Fig. 45. Shell-type transformer.

23. Materials. In electronic power transformers cores are made chiefly of silicon steel. In usual practice, it is necessary to avoid reaching saturation flux densities, because high exciting currents produce high winding IR drops, high losses, low efficiency, and large size. Curves of induction and core loss are available from manufacturers of laminations. Grades and thickness are designated by numbers such as
Fig. 46. Core loss at high induction. Armco Trancor M15 grade, 29 gage.

Armco Trancor M15 and Allegheny Transformer A. Hot-rolled silicon-steel laminations are available in 0.014-in., 0.019-in., and 0.025-in. thicknesses, with silicon content of approximately 3 to 4 per cent, and with core losses ranging from 0.6 to 1.2 watts per pound at 10,000 gausses, 60 cps (64,500 lines per square inch). Figures 46 and 47 are

core-loss and exciting v-a/lb for a widely used grade of electronic transformer core steel at 60 cps.

Much work has been done in developing grain-oriented core materials. These materials have a composition similar to that of older nonoriented core material, but grains in the material are oriented by cold rolling. When magnetic flux is established in the lamination, the grains must be aligned in the same direction. If the grains are
FIG. 47. Exciting rms volt-amperes per pound. Armco Trancor M15 grade, 29 gage.
FIG. 48. Induction and core-loss curves of silicon steel and Westinghouse Hipersil at 60 cycles.

already oriented in this direction during the rolling process, much smaller magnetizing force is required to produce the desired flux. Coercive force and hysteresis loss are smaller than in nonoriented steel and permeability is greater.

The development of grain-oriented silicon steel has had a marked effect on transformer size and performance. To illustrate this effect, a comparison is made below between the older nonoriented steel (termed, for simplicity, silicon steel) and Hipersil, a cold-rolled steel in which grain orientation is carried out to a high degree. If core

flux flows in the grain-oriented direction, high core inductions may be realized. Type C cores fulfill this requirement, because the strip is wound in the same direction as the flux path.

The material is rolled in three major thicknesses:

No. 29 gage (about 12 to 14 mils thick) for frequencies up to 400 cps
5 mils thick for frequencies 400 cps and higher
2 mils thick for frequencies in the low and medium r-f bands

Probably the most remarkable property of this material is its high saturation point. In Fig. 48 the comparison is given in terms of a hypothetical 60-cycle working induction using high-grade, conventional silicon steel. If this value is assumed to be 100 per cent, the induction obtained with grain-oriented steel is 130 to 150 per cent, with no increase in magnetizing force. Better space factor can be obtained with strip-wound cores, as is indicated in Table 2.

Table 2. Hipersil Core Data

Hipersil	Thickness, in.	Typical Hipersil space factor, %*	Typical space factor for silicon steel, %*
C-97	0.013	95	90
C-95	0.005	90	80
C-91	0.002	85	70

* Refers to percentage of core volume occupied by metal. The Hipersil figure is for type C cores, and the silicon steel figure is for punched laminations.

Core-loss and exciting v-a/lb for 29-gage Hipersil are plotted in Figs. 49 and 50. Joint reluctance is neglected in Fig. 50.
Fig. 49. Core loss in C-97 Hipersil cores (29 gage).

Operating flux density depends upon several factors, such as core material, gage, supply frequency, and operating temperature. For 60 cps, hot-rolled silicon steel laminations may be used at flux densities in the vicinity of 12 kilogausses, and Hipersil in type C cores at about 16 kilogausses. Some manufacturers punch laminations

from grain-oriented sheet; cores of this material may be operated at flux densities intermediate between 12 and 16 kilogausses. The exact value depends on the lamination shape. Lower losses and exciting v-a occur in laminations with long core windows, and with window length in the cold-rolling direction.

At the 400-cycle supply frequency, either 4- or 5-mil Hipersil type C cores offer considerable weight saving when compared with hot-rolled laminations. For the smaller aircraft transformer ratings, it is practicable to operate 4-mil Hipersil at 17 kilogausses and at the lowest supply frequency. Frequency is emphasized because of the relatively wide frequency tolerances encountered in aircraft. With operating frequency lower than nominal, excessive magnetizing current may be drawn by the transformer unless it is designed for this frequency. The result then is overheating or low output voltage.
Fig. 50. A-c excitation curve, typical data. C-97 Hipersil cores (29 gage).

24. Windings. Current density in the winding copper is sometimes estimated for design purposes by rules such as 1,000 cir mils per amp. These rules are useful in picking out a first choice of wire size for a given current requirement but should not be regarded as final. Instead, the temperature rise, regulation, or other performance criterion should govern the final choice of wire size. In Fig. 51 the circular mils per ampere are plotted for small enclosed dry-type transformers with Hipersil cores and a winding temperature rise of 55°C; it can be seen to vary appreciably over this range of sizes.

Space occupied by the wire depends on the wire insulation as well as on the copper section. This is especially noticeable in small wire sizes. Table 3 gives the bare and insulation diameters for several common kinds of wire, and Table 4 gives the turns per square inch of winding space. Space usually can be saved by avoiding cotton or silk wire covering and instead using enameled wire with paper layer insulation as in Fig. 52. Thickness of layer paper may be governed by layer voltage; it is good practice to use 50 volts per mil of paper. In coils where layer voltage is low, the paper thickness is determined by the mechanical strength necessary to produce even layers and a tightly wound coil. Table 5 gives the minimum paper thickness based on this consideration.

Space factor may refer to linear spacing, as across a layer, or to the total coil-section area. It is more convenient to use linear space factor in designing layer-wound coils and area space factor in random-wound coils. The values in each case depend largely on the method of winding. For example, it is possible to wind No. 30 enameled wire
FIG. 51. Wire size in windings of small enclosed 60-cycle transformers.
FIG. 52. Paper-insulated coil.

with 97 per cent linear space factor by hand, but with only 89 per cent on an automatic multiple-coil winding machine. Moreover, values of space factor vary from plant to plant. An average for multiple-coil machines is given in Table 5.

Mean length of turn must be calculated for a coil to find its resistance. This may be found by referring to the side view of Fig. 52. Note that there is a small clearance space between core and coil form or tube. Let d be the core tongue and W the stack.

Table 3. Insulated-wire Sizes

B & S gage	Bare diam	Diam of insulated wire								Area, cir mils	Ohms per 1,000 ft at 25°C	Ft per ohm at 25°C	Lb per 1,000 ft

Suppose there are several concentric windings. The length of mean turn of a winding V at distance r from the core and having height D is

$$MT = 2W + 2d + 2\pi\left(r + \frac{D}{2}\right)$$
$$= 2(W + d) + \pi(2\Sigma D + D) \qquad (10)$$

where ΣD is the sum of all winding heights and insulation thicknesses between winding V and the core.

8	57	57						

The mean turn of a winding U just below winding V ordinarily is calculated before that of V. This simplifies the calculation of winding V, the mean turn of which is

$$MT_v = MT_u + \pi(D_u + D_v + 2c) \tag{11}$$

where c is the thickness of insulation between U and V.

Allowance must be made, with many coil leads, for bulging of the coil at the ends and consequent increase of mean turn length.

The placement, insulation, and soldering of leads constitute most important steps in coil manufacture. When coils are wound one at a time, the leads can be placed in the coil while it is being wound. The start lead may be placed on the coil form, suitable insulation may be placed over it, and coil turns may be wound over the insulation. Tap leads can be arranged in the same way. Finish leads must be anchored by means of tape, string, or yarn, because there are no turns of wire to wind over them.

In multiple-wound coils, the leads must be attached after the coils are wound. Extra wire on the start turn is pulled out of the coil and run up the side as shown in Fig. 53, with separator insulation between wire extension and coil. Outer insulation covers the wire extension up to the lead joint. A pad of insulation is placed under the joint, and one or more layers of insulation, which insulate and anchor the joint, are wound over the entire coil and the lead insulation. Electrical-grade scotch tape is widely used for anchoring leads. It is important to avoid corrosive adhesives.

Leads should be large enough to introduce only a small amount of voltage drop and should have insulation clearances adequate for the test voltage. These clearances can be found as explained in Sec. 25. In high-voltage transformers it would often be easy to seal the windings if there were no leads; hence lead placement calls for much care and skill. Leads and joints should also be mechanically strong enough to withstand winding, impregnating, and handling stresses without breakage.

25. Insulation. Three classes of insulation are used in dry-type transformers. Class A insulation is organic material such as paper, cotton, silk, varnish, or wire enamel. Class B insulation is mica, asbestos, glass, porcelain, or other inorganic

material with organic binders such as varnish for embedding the insulation. A small amount of other class A material is permissible in a class B coil "for structural reasons," but it should be kept to a minimum.

In general, the vital difference between these classes of insulation is one of operating temperature. Glass-covered wire is preferable to asbestos for space reasons; it is available in approximately the same dimensions as cotton-covered wire. Built-up mica is the usual insulation wrapper material. With special bonds it is flexible enough to wind over coils or layers of wire. Stiff mica plate for lead insulation and mica tubing for coil forms are usually bonded with heat-resistant varnish. Class B insulating material is more expensive than class A and is used only when the advantages outweigh the cost.
FIG. 53. Start-lead insulation in multiple-wound coils.

A third class of insulation is the *silicones*, which are organic silicates with remarkable thermal and mechanical properties. These materials are coming into use at operating temperatures approaching 200°C. Silicone-treated cloth, silicone rubber, and silicone varnish are already in use. Under development are silicone wire enamel and silicone-bonded mica. They are generally designated as class H insulation.

For apparatus having long service life, AIEE Standard 1 limits the "hottest spot" temperature of impregnated coils as follows:

Class A insulation............	105°C
Class B insulation............	130°C
Class H insulation............	200°C

The usual figure given for dielectric strength is the breakdown value in rms volts at 60 cps in a 1-min test. It is not possible to operate class A insulation anywhere near this value because of the cellular structure of all organic materials. Even after these materials are treated with varnish, many small holes exist throughout a coil structure which ionize and form corona at voltages far below breakdown. With class A insulation (organic materials), the designer must be governed more by resistance of the insulation to corona over a long period than by breakdown strength of the insulation in a 1-min test. For example, a 20-mil thickness of treated cloth will withstand 10,000 volts for 1 min. However, corona starts at 1,250 volts, and operation at any higher voltage would puncture the insulation in a few weeks. It is much wiser to keep a

reasonable margin, say 20 to 30 per cent, below the corona limit than to use a fraction of the 1-min breakdown test. Approximate voltages at which corona is audible are plotted in Fig. 54 as a function of insulation thickness.

Although solid insulation dielectric strength is important, the usual bottleneck for high voltage is creepage distance, such as margins between wire and core along the layers of insulation, or margins between lead joints and frame along the leads and coil sides. A common way of increasing the direct creepage distance across the margins is to use an insulating channel as in Fig. 55*a*. This is especially helpful when the part of the coil adjacent to the core tongue is at low potential and the upper part is at high potential, as in some plate transformers. When the whole coil is at high potential it may be insulated by taping the coil. This is expensive and is avoided wherever creepage safely provides the necessary insulation strength.

Insulation between the start (or finish) turn of the first layer and the core consists of creepage along the margin plus the thickness of the coil form. If, however, the coil lead is brought across the margin and up the side of the coil, the only creepage
Fig. 54. Corona limit for treated cloth and paper.

distance is the thickness of the coil form. In low-voltage coils this may be enough; in higher-voltage coils, a barrier of insulating material is needed between the coil form and the core, under the spot where the lead is brought out. Such a barrier is provided by outer insulation in Fig. 53. Dimensions of the insulating barrier should be such that a distance at least equal to the coil margin should intervene between the start lead and the core in all directions. The thickness may be the same as the coil form.

In any coil where the finish lead is at the top, there is less difficulty in insulating it. The finish lead has a longer creepage distance to the core if the height of the coil is a greater distance than the margin. It is necessary to avoid using materials on the sides of the coil which would result in any decrease of dielectric strength. In this respect, the creepage strength of some materials with high puncture strength is not good. The last layer of wire may be insulated from the core with a channel as in Fig. 55*a*.

When practical coil margins, even with barriers, are insufficient to support the induced or applied voltage, coils are taped as in Fig. 55*b*. Taping is the most time-consuming but the safest method of insulation.

After a coil is wound it should be impregnated in some sort of insulating liquid which hardens after filling. This is done for several reasons. First, it protects the wire from movement and possible mechanical damage. Second, it prevents the entrance of moisture and foreign matter which might corrode the wire or cause insulation deterioration. Third, it increases the dielectric strength of fibrous insulating materials. Fourth, it assists in heat dissipation from the coil. Single-layer coils may be

dipped in the liquid, drained, and dried, but deeper, thicker coils require the use of vacuum to remove air from the coil and admit the liquid to all parts of the interior. The best mechanical result is obtained when coils are assembled with cores before treatment.

Coils having little or no temperature rise in normal use are impregnated with chemically neutral mineral wax. The wax is melted in a sealed tank and is drawn into another tank in which preheated coils have been placed, and a vacuum is maintained. Coils are removed from the tank, drained, and allowed to cool. Wax treatment provides good dielectric qualities and moisture protection. It is a quick, simple process.

Transformers having operating temperatures of 65°C or higher are impregnated with varnish. Varnish of good grade and close control is essential to achieve thorough filling and dry coils after impregnation. Solventless varnishes, which polymerize to a hard state by baking, are notably useful for the purpose. Filling of the coil may be accomplished by casting the transformer in a mold, or by encapsulation. Encapsulation is readily adapted to irregular coil surfaces and is accomplished by a leakproof
FIG. 55. (*a*) Use of insulation channel. (*b*) Taped coil.

coat before filling. In either process, a good vacuum is necessary to ensure complete filling.

Silicone materials are moisture-resistant. Basic insulation should be inorganic or silicone-treated cloth, tape, laminated sheets, and tubes. Through the use of silicones, some transformers may be designed to have very small dimensions for their ratings. This may be achieved most successfully if the coil insulation comprises only silicone or inorganic materials, including impregnation with silicone varnish. Dielectric strength of silicones is about the same as that of class A materials. Hence the thickness of silicone coil insulation is similar to that for organic materials.

26. Ratings and Color Codes. Core area depends upon voltage, induction, frequency, and turns. For a given frequency and grade of core material, core area depends upon the applied voltage. Window area depends upon coil size or, for a given voltage, upon the current drawn. Since window area and core area determine size, there is a relation between size and v-a rating.

Figure 56 shows the relation between size and rating for small, enclosed, low-voltage, two-winding, 60-cycle transformers having Hipersil cores and class A insulation and operating continuously in a 40°C ambient. The size increases for the same v-a over that in Fig. 56 for any of the following reasons:

High voltage	Silicon-steel cores
High ambient temperature	Low regulation
Lower frequency	More windings

The size decreases for

Higher frequencies	Open-type units
Class B insulation	Intermittent operation

If low-voltage insulation is assumed, two secondary windings reduce the rating of a typical size by 10 per cent; six secondaries by 50 per cent. The decreased rating is due partly to space occupied by insulation and partly to poorer space factor.
Fig. 56. Size of enclosed 60-cycle transformers.

Transformer Color Code. The leads to transformers of the several types have been standardized as shown below when leads, rather than terminals, are used for external connections.

Power Transformers

Use	Color
Two-wire primary	Both leads black
Tapped primary	Start of winding, black; tap 50/50 black and yellow; finish, 50/50 black and red; if tap is not at center, it is to be nearer the finish end
Rectifier filament	Both leads yellow; tap if used, 50/50 yellow and blue
Rectifier plate	Both leads red; tap 50/50 yellow and red
Amplifier filament winding No. 1	Both leads green; tap if used, 50/50 green and yellow
Amplifier filament winding No. 2	Both leads brown; tap if used, 50/50 brown and yellow
Amplifier filament winding No. 3	Both leads slate; tap if used, 50/50 slate and yellow

I-f Transformers

Use	Color
Plate	Blue
B+	Red
Grid or diode	Green
Grid return or diode return	Black
Secondary tap if used	Green and black

A-f Transformers

Use	Color
Plate	Blue
B+	Red
Other plate for push-pull, start of winding	Blue or brown
Grid or high side of moving coil	Green
Return or low side of moving coil	Black
Other grid for push-pull, start of winding	Green or yellow

27. Simple Transformer Design. It is important that design work be done systematically to save time and to afford a ready means of finding calculations at a later date.

Suppose that a transformer is required to supply filament power for four single-phase full-wave rectifiers having output voltages of 2,000, 500, 250, and 250 volts, respectively, with choke-input filters, as follows:

Primary voltage 100, frequency 60 cycles, four secondaries as follows:

S1:	5 volts	13.5 amp	Insulated for +2,000 volts d.c.
S2:	2.5 volts	10 amp	Insulated for + 500 volts d.c.
S3:	5 volts	3 amp	Insulated for + 250 volts d.c.
S4:	5 volts	2 amp	Insulated for + 250 volts d.c.

Ambient temperature: 40°C

First comes the choice of a core. Data such as those in Fig. 56 are helpful, and so is experience in the modification of such data by the specified requirements. The core selected is a 2-in. stack of laminations described in Fig. 57, and has enough heat dissipation surface for this rating. For silicon steel, an induction of 70,000 lines per square inch is practical. The primary turns

$$N_1 = \frac{E \times 10^8}{4.44 f A_c B} \tag{12}$$

where E = primary voltage, f = line frequency, A_c is the core cross-sectional area, or product of the core tongue width and stack dimension, and B is the core induction. In this transformer, with 90 per cent stacking factor, $A_c = 2 \times 0.9 \times 1.375 = 2.48$ sq in., and the primary turns are found to be 216.

From the sum of the individual v-a figures for windings S_1 to S_4, the transformer rating is found. To it is added an estimate of losses (18 v-a) to obtain the input v-a (135.5) and the primary current (1.36 amp).

Next an estimate of the regulation is made (10 per cent) and added to unity to obtain the multiplier 1.1 in the estimate of secondary turns. From the currents required the wire size for each winding is chosen: P, No. 20; S_2, No. 13; S_3, No. 18; and S_4, No. 20. Round enameled wire is used for each winding except S_1, and for it No. 12 square wire is used to save space. The largest wire is placed next to the coil form to prevent damage in winding to the smaller wires.

Next find out whether the wire chosen will fit in the core window space. Winding height D is calculated for each winding. For each secondary this is the wire diameter, because the wire is wound in a single layer. D for S_1 is slightly larger than the wire dimension to allow for the bulge that occurs when square wire is wound. Twelve turns of S_1 occupy about 1¼ in. of horizontal winding space. The core window is 2¼ in. wide. Subtract ⅛ in. for clearance, leaving 2⅛ in. total coil width. Margins on each side of S_1 are ½(2⅛ − 1¼) = 7⁄16 in. This provides over 8-kv breakdown strength, which is well above the 5-kv test voltage of S_1. Other secondary windings have lower test voltages and wider margins and more than adequate creepage distances.

The 1⁄16-in. Micarta rectangular coil form has a corona voltage of 2,700 rms, which affords about 23 per cent safety factor over the normal operating voltage at the tube fila-

ments. Over S_1 are wound six wraps of 0.010-in.-thick treated cloth, which has 2,600-volt corona limit. S_2 supplies a filament at 500 volts of the same polarity as S_1. Hence only 1,500 volts d.c. or 1,660 volts a.c. occurs across this insulation.

Over S_2 are wound two wraps, over S_3 two wraps, and over S_4 are wound three wraps, all of 0.010-in.-thick treated cloth so that the total cloth thickness amounts to 0.150 in.

The primary winding is wound without layer insulation and with an area space factor of 70 per cent. Cotton is wound in with the wire to form walls 3/16 in. thick on either side of the primary; this accounts for the low space factor and for a 1¾-in. winding traverse. The coil is finished with two layers of treated cloth, a layer of 0.010-in. fishpaper for mechanical protection, and a 0.025-in. serving of untreated cotton yarn or tape to hold it together. The total winding adds up to 0.751 in., leaving 0.124 in. clearance, about the right allowance for winding slack for four secondaries.

Mean turns are figured from Eqs. (10) and (11), with 5 per cent incremental increase of S_2, S_3, and S_4 for leads. With the mean turn values the winding resistances, weights in
FIG. 57. Dimensions and coil section of filament transformer.

copper, and IR and I^2R for each winding can be found. To S_1, S_2, and S_3 winding resistance is added lead resistance, and the total figure is the sum of the two in each case. Total copper loss is multiplied by 1.3 to correct for 75°C operating temperature. The core weight is 6.8 lb, and the grade of steel used has 1.17 watts per pound at 70,000 lines per square inch. This gives a core loss of 8 watts, and a total of copper and core loss of 20 watts. Added to the input, these losses give efficiency = 85 per cent, which is in accordance with Fig. 56 for this rating. Output voltages on first trial range from 0 to 4 per cent high. S_2 voltage is correct but out of line with the rest. Changing S_2 leads to a larger size makes the per cent voltage drops more nearly alike, and increasing the primary turns to 223 brings all output voltages to correct value within 1.2 per cent. Filament voltage should be kept within 2 per cent for some tubes, to allow for meter error. Primary voltage per layer is equivalent to about 22.7 volts per mil of wire enamel, which is safe practice.

28. Anode Transformer Design. Anode transformers differ from filament transformers in several respects.

1. *Currents* are nonsinusoidal.
2. *Leakage inductance* not only determines output voltage but also affects rectifier regulation in an entirely different manner than with a straight a-c load.
3. *Half-wave rectifiers* carry unbalanced d.c.; this may necessitate less a-c flux density, and larger transformers, than full-wave rectifiers, especially in limited power supplies like aircraft generators. Otherwise, wave-form distortion may result.

4. ***Single-phase full-wave rectifiers with two anodes*** have higher secondary volt-amperes for a given primary v-a rating than a filament transformer.
5. Induced secondary voltage is much higher.

For this last reason, volts per layer are higher in anode transformers, and core windows having proportionately greater height and less width than those in Fig. 57 are often preferable. This trend runs counter to the conditions for low leakage inductance and makes it necessary to interleave the windings. Figure 58 shows the windings of a single-phase full-wave rectifier transformer with the primary interleaved between halves of the secondary. This arrangement is especially adaptable to transformers with grounded center tap. The primary-secondary insulation can be reduced to the amount suitable for primary to ground. This is called *graded* insulation.

Fig. 58. Dimensions and coil section of anode transformer. Construction shown is for shell-type transformer with two Hipersil cores.

Vibrator transformers[1] are similar in design to low-voltage anode transformers, but generally the core induction is lower (8 to 10 kilogausses). Magnetizing current is thus kept small, to aid the vibrator contacts at the instant of switching. This requirement means that vibrator transformers are somewhat larger than anode transformers of the same rating.

In Fig. 58, all flux which follows the core path l_c is mutual flux. Leakage flux is the relatively small flux which threads the secondary winding sections, enters the core, and returns to the other side of the secondaries, without linking the primary. The same is true of flux linking only the primary winding. But it is almost impossible for flux to leave the primary winding, enter the core, and reenter the primary without linking part of the secondary also. The more the primary and secondary windings are interleaved, the less leakage flux there is, up to the limit imposed by flux in the spaces c between sections. These spaces contain leakage flux also; indeed, if there is much interleaving or if the spaces c are large, most of the leakage flux flows in them. Large coil mean-turn length, short winding traverse b, and tall window height a all increase leakage flux.

Leakage inductance may be calculated by

$$L_S = \frac{10.6N^2MT(2nc + a)}{10^9n^2b} \tag{13}$$

where L_S = leakage inductance of both windings, henrys, referred to the winding having N turns
MT = mean length of turn for whole coil, in.
n = number of dielectrics between windings (n = 2 in Fig. 58)
c = thickness of dielectric between windings, in.
a = winding height, in.
b = winding traverse, in.

Windings for simple low-voltage 60-cycle transformers may be chosen from winding charts of Fig. 59[2] based upon these conditions:

1. Two untapped concentric windings; primary wound first
2. Operating voltage in both windings less than 1,000 volts
3. Power-supply frequency 60 cycles

[1] EIA Standard RS-177, "Vibrator Power Transformers," February, 1957.
[2] Lee, Reuben, and N. E. Mullinix, Transformer Design Chart, *Trans. IRE*, PGCP, 10, April, 1955.
4. Maximum temperature rise 40°C in 65°C ambient
5. Resistive loads
6. Equal I^2R losses in primary and secondary
7. Solventless-resin-impregnated coils
8. Open-type assemblies like those of Fig. 44
9. Grain-oriented silicon-steel cores

Winding regulation in the two smallest transformers is limited to 15 per cent, and in the next two larger sizes to 10 per cent. In still larger sizes, the 40°C temperature limit held the regulation to less than 10 per cent.
FIG. 59. Low-voltage 60-cycle transformer design chart.

In using the chart, ratings rarely fall exactly on the v-a values assigned to each core. Hence a core is generally chosen with somewhat greater than required rating. Lower regulation and temperature rise than maximum then result. Wire size in quadrant I also increases in discrete sizes, and if the chart indication falls between two sizes the smaller size should be used.

Instructions for Using Fig. 59

1. Choose a core from Table 6 which has a v-a rating equal to or greater than that required.
2. From rated primary and secondary voltages, find number of turns for both windings in quadrant IV.
3. From rated primary and secondary voltages, find wire size for both windings in quadrant I.
4. Project turns across to quadrant III to obtain winding resistances.

Table 6. Transformer Size, Rating, and Regulation

Core	Max v-a rating	% regulation	Total weight, lb	Over-all dimensions, in.
1	5	15	0.38	1¾ × 1¾ × 1¾
2	10	15	0.68	1⅞ × 2⅜ × 1¾
3	25	10	1.2	2¼ × 2⅞ × 2¼
4	50	10	2.2	2½ × 3⅛ × 2½
5	100	8	3.8	3⅛ × 3¾ × 3
6	200	6	6.4	3⅞ × 4¾ × 3⅝
7	350	4	11.0	4⅜ × 5⅜ × 4
8	500	3	15	5⅛ × 6⅛ × 5
9	1,000	2.2	24	5⅞ × 6¾ × 6⅛
10	1,600	1.8	36	7¼ × 8¼ × 7½
11	3,200	1.2	75	9¾ × 12¾ × 8

Departures from the assumed conditions preclude direct application of Fig. 59, but it is still useful as a starting point. For some common modifications, the following notes apply:

1. For each additional secondary winding reduce core maximum rated v-a by 10 per cent. Choose wire size from quadrant II.
2. For 50-cycle transformers, reduce core maximum rated v-a 10 per cent.
3. When permissible temperature rise is higher than 40°C, core maximum v-a equal (v-a in table) $\times \sqrt{\text{temperature rise}/40°\text{C}}$.

Example: A transformer is required for 115/390 volts, 60 cycles, to deliver 77 volt-amperes. This rating falls between the maxima for cores 4 and 5. Using core 5 at 115 volts, read, from Fig. 59, for the primary, 440 turns of No. 22 wire and 3 ohms resistance; for the secondary, 1,700 turns of No. 27 wire and 40 ohms resistance.

29. Power-transformer Tests. A power transformer is tested to discover whether it will perform as required, or whether it will give reliable service life. Some tests perform both functions.

1. *D-c Resistance.* This test is usually made on transformers at the factory as a check on the correctness of wire size.

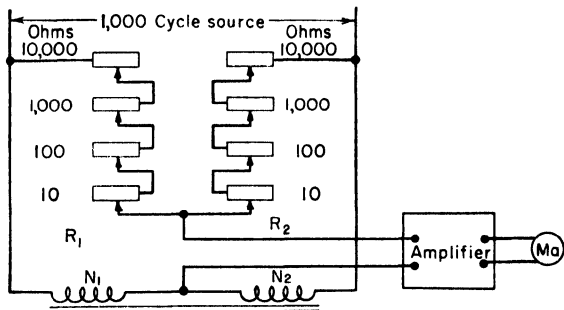
2. *Turns Ratio.* Once the correct number of turns in each winding is established, correct output voltage can be assured for a coil of given design by measuring the turns. A simple way of doing this is by use of the turns-ratio bridge in Fig. 60. If the turns are correct, the null indicated by the meter occurs at a ratio of resistances


FIG. 60. Turns-ratio bridge.

$$R_1/R_2 = N_1/N_2 \tag{14}$$

If there is an error in the number of turns of one winding, the null occurs at the wrong value R_1/R_2. A filtered source of 1,000 cps is preferable to one of 60 cps for this test.

An accuracy of 0.1 per cent can usually be attained with four-decade resistances. Polarity of winding is also checked by this test, because the bridge will not balance if one winding is reversed.

3. *Open-circuit Inductance (OCL).* There are several ways of measuring inductance. If the Q is high, the check may be made by measuring the current drawn by an appro-

priate winding connected across a source of known voltage and frequency. This method is limited to those cases where the amount of current drawn can be measured. A more general method makes use of an inductance bridge.

4. *Temperature Rise.* Tests to determine whether a transformer overheats are made by measuring the winding resistances before and after a heat run, during which the transformer is loaded up to its rating. Power is applied long enough to allow the transformer temperature to become stable; this is indicated by thermometer readings of core or case temperature taken every half hour until successive readings are the same. Ambient temperature at a nearby location should also be measured throughout the test. The average increase in winding resistance furnishes an indication of the average winding temperature.

5. *Regulation.* It is possible to measure voltage regulation by connecting a voltmeter across the output winding and reading the voltage with load off and on. This method is not accurate because the regulation is usually the difference between two relatively large quantities. Better accuracy can be obtained by multiplying the rated winding currents by the measured winding resistances. If the winding reactance drop is small this works well for resistive loads. To measure reactance voltage drop, a short-circuit test is used. With the secondary short-circuited, sufficient voltage is applied to the primary to cause rated primary current to flow. The quotient E/I is the vector sum of winding resistances and reactances. Reactance is found from

$$X = \sqrt{Z^2 - R^2} \tag{15}$$

where R includes the resistance of both windings and the meter.

Sometimes it is more convenient to measure the leakage inductance with secondary short-circuited on a bridge and multiply by $2\pi f$.

6. *Output Voltage.* Although the method described under (5) above is accurate for two-winding transformers, it is not applicable to multisecondary transformers unless they are tested first with newly calibrated meters to see that all windings deliver proper voltage at full load. Once this is established, values of winding resistance and reactance thereafter can be checked to control the voltage.

7. *Losses.* Often it is possible to reduce the number of time-consuming heat runs by measuring losses. The copper loss is readily calculated by multiplying the measured values of winding resistance (corrected for operating temperature) by the squares of the respective rated currents. Core loss is measured with open secondary by a low-reading wattmeter at rated voltage in the primary circuit. If these losses correspond to the allowable temperature rise, the transformer is safely rated.

8. *Insulation.* If insulation withstands twice normal voltage plus 1,000 volts rms at 60 cps for 1 min, reasonable insulation life is usually obtained. It is possible for a transformer to be extremely underinsulated and still pass this test; conversely, there are conditions under which the rule would be a handicap. Therefore it can only be considered as a rough guide.

The manner of making insulation tests depends upon the transformer. Low-voltage windings can be tested by shorting the terminals and applying the test voltage from each winding to core or case with other windings grounded. Filament transformers with secondaries insulated for high voltage may be tested in similar manner. But a high-voltage plate transformer with grounded center tap requires unnecessary insulation if it is tested by this method. Instead, a nominal voltage of, say, 1,500 volts is applied between the whole winding and ground; after that the center tap is grounded and a voltage is applied across the primary of such value as to test the end terminals at twice normal plus 1,000 volts. Similar test values can be calculated for windings operating at d-c voltages other than zero. Such a test is called an *induced voltage test.* It is performed at higher than normal frequency to avoid saturation. An advantage of induced voltage testing is that it tests the layer insulation.

If insulation tests are repeated one or more times they may destroy the insulation, because insulation breakdown values decrease with time. Successive applications of

test voltage are usually made at either decreased voltage or decreased time. In view of their dubious value, repeated insulation tests are best omitted.

Corona tests are not open to this objection. A voltage 5 per cent higher than normal is applied to the winding, and the leads are run through blocking capacitors to the input of a sensitive radio receiver. EIA standard noise values for this test are given in Table 7.

Table 7. Corona Voltage*

Up to 8.6	1,000
8.61 to 15	2,500

* EIA Standard TR-102-B, "Power Transformers for Radio Transmitters."

30. Reactors. Reactors are used in electronic power equipment to smooth out ripple voltage in d-c supplies. Therefore they carry d.c. in the coils. It is common
FIG. 61. Normal and incremental permeability of 4 per cent silicon steel.

practice to build such reactors with air gaps in the core to prevent d-c saturation. The air gap, size of core, and number of turns depend upon three interrelated factors: inductance desired; d.c. in the winding; and a-c volts across the winding.

The number of turns, the direct current, and the air gap determine the d-c flux density, whereas the number of turns, the volts, and the core size determine the a-c flux density. If the sum of these two flux densities exceeds saturation value, noise, low inductance, and nonlinearity result. Therefore a reactor must be designed with knowledge of all three of the conditions above.

Magnetic flux through the coil has two component lengths of path: the air gap l_g and the length of the core l_c. The core length l_c is much greater geometrically than l_g, as indicated in Fig. 58, but the two components do not add directly because their permeabilities are different. In the air gap, the permeability is unity, whereas in the core its value depends on the degree of saturation of the iron. The effective length of the magnetic path is $l_g + (l_c/\mu)$, where μ is the permeability for the steady or d-c component of flux.

Reactor design is, to a large extent, the proportioning of values of air gap and magnetic path length divided by permeability. If the air gap is relatively large, the reactor inductance is not much affected by changes in μ; it is then called a *linear* reactor. If the air gap is small, changes in μ due to current or voltage variations cause inductance to vary; then the reactor is nonlinear.
Fig. 62. Reactor energy per unit volume vs. ampere-turns per inch of core.

The curve in Fig. 61 marked μ is the normal permeability of 4 per cent silicon steel for steady values of flux, in other words, for the d-c flux in the core. It is four to twenty times as great as the incremental permeability μ_Δ for a small alternating flux superposed upon the d-c flux. The ratio of μ to μ_Δ gradually increases as d-c flux density increases.

Because of the low value of μ_Δ for minute alternating voltages, the effective length of magnetic path $l_g + (l_c/\mu_\Delta)$ is considerably greater for alternating than for steady flux. But the inductance varies inversely as the length of a-c flux path. If, therefore, the incremental permeability is small enough to make l_c/μ_Δ large compared with l_g, small variations in l_g do not affect the inductance much. For this reason the exact value of the air gap is not important with low alternating voltages.

Reactor size, with a given voltage and ratio of L to R, is proportional to the stored energy LI^2. For the design of reactors carrying d.c., that is, the selection of the right number of turns, air gap, and so on, a simple method was originated by C. R. Hanna.[1] By this method, magnetic data are reduced to curves such as Fig. 62, plotted between LI^2/V and NI/l_c, from which reactors can be designed directly.

The various symbols in the coordinates are:

L = a-c inductance, henrys
I = d.c., amp
V = volume of iron core, cu in.
= $A_c l_c$ (see Fig. 58 for core dimensions)
A_c = cross section of core, sq in.
l_c = length of core, in.
N = number of turns in winding
l_g = air gap, in.

Example: Assume a stack of silicon-steel laminations having a cross section ⅞ by ⅞ in., and with iron filling 92 per cent of the space. The length of the flux path l_c in this core is 7½ in. How many turns of wire and what air gap are necessary to produce 70 henrys with 20 ma d.c. in the winding?

$$A_c = (0.875)^2 \times 0.92 = 0.71 \text{ sq in.}$$
$$V = 0.71 \times 7.5 = 5.3$$
$$\frac{LI^2}{V} = \frac{70 \times 4 \times 10^{-4}}{5.3} = 53 \times 10^{-4}$$

[1] Hanna, C. R., Design of Reactances and Transformers Which Carry Direct Current, *J. AIEE*, **46**, 128, February, 1927.

In Fig. 62 the abscissa corresponding to $LI^2/V = 53 \times 10^{-4}$ is $NI/l_c = 25$ for silicon steel. The ratio of air gap to core length l_g/l_c is between 0.0005 and 0.001.

$$NI/l_c = 25$$
$$N = (25 \times 7.5)/0.020 = 9{,}375 \text{ turns}$$

The total air gap is nearly $0.001 \times 7\frac{1}{2}$ or 7.5 mils; the gap at each joint is half of this value, or 3.75 mils.

The conditions underlying Hanna's method of design are met in most applications. In receivers and amplifiers working at low audio levels, the alternating voltage is low and hence the alternating flux is low compared with the steady flux. Even if the alternating voltage is of the same order as the direct voltage, the alternating flux may be low, especially if a large number of turns are necessary to produce the required inductance; for a given core the alternating flux is inversely proportional to the number of turns. D-c coil resistance is usually fixed by the regulation or size requirements. Heating seldom affects size.

31. Reactors with Large A-c Flux. With higher voltages, it often happens that the a-c flux is no longer small compared with the d-c flux. This occurs in high-impedance circuits where the d.c. is low and the alternating voltage is high. The inductance increases by an amount depending on the values of a-c and d-c fluxes. In a reactor working near the saturation point, increasing a-c flux soon adds to the saturation, which prevents further inductance increase. Saturation of this sort may be avoided by limiting the value of the d-c flux.

Saturation could be reduced by increasing the air gap somewhat. Average permeability increases, and so does the inductance, if the maximum flux density is kept low enough to avoid saturation. Conversely, if saturation is present in a reactor, it is manifested by a decrease in inductance as the d.c. through the winding is increased from zero to full-load value.

In a reactor having high a-c permeability the equivalent length of core l_c/μ is likely to be small compared with the air gap l_g. Hence, it is vitally important to keep the air gap close to its proper value. This is, of course, in marked contrast to reactors not subject to high a-c induction.

It is important that the inductance be the right value. Rectifier regulation can be improved by the use of swinging or tuned reactors. In a swinging reactor, saturation is present at full load; therefore the inductance is lower at full load than at no load. The higher inductance at no load is available for the purpose of improving voltage regulation. The same result is obtained by shunt-tuning the reactor, but here the inductance should be constant from no load to full load to preserve the tuned condition.

In swinging reactors, all or part of the core is purposely allowed to saturate at the higher values of d.c. to obtain high inductance at low values of d.c. They are characterized by smaller gaps, more turns, and larger size than reactors with constant inductance ratings. Sometimes two parallel gaps are used, the smaller of which saturates at full d.c. When the function of the reactor is to control current by means of large inductance changes, no air gap is used. Design of such reactors is discussed in Sec. 33.

The insulation of a reactor depends on the type of rectifier and how it is used in the circuit. Three-phase rectifiers, with their low ripple voltage, do not require the turn and layer insulation of single-phase rectifiers. If the reactor is placed in the ground side of the circuit one terminal requires little or no insulation to ground, but the other terminal may operate at a high voltage to ground. In single-phase rectifiers the peak voltage across the reactor is E_{dc}, so the equivalent rms voltage on the insulation is $0.707E_{dc}$. But for figuring B_{max} the rms voltage is $0.707 \times 0.67E_{dc}$.

32. Linear Reactor Design. A method of design for linear reactors based on three assumptions follows.

1. The air gap is large compared with l_c/μ, μ being the d-c permeability.
2. A-c flux density depends on alternating voltage and frequency.
3. A-c and d-c fluxes can be added or subtracted arithmetically.

Under these conditions, inductance may be found from

$$L = \frac{3.19N^2A_c \times 10^{-8}}{l_g + (l_c/\mu_\Delta)} \quad \text{henrys} \tag{16}$$

where N is number of turns and dimensions are in inches. Term A_c in Eq. (16) is greater than in Eq. (12) because of the space factor of the laminations; if the gap is large A_c is greater still because the flux across it fringes. With large gaps, inductance is nearly independent of μ_Δ. With small gaps, permeability largely controls. There is always a certain amount of gap even with punchings stacked alternately in groups of 1. Table 8 gives the approximate gap equivalent of various degrees of interleaving laminations for magnetic path l_c of 5.5 in.

Table 8. Equivalent Gaps with Interleaved Laminations

0.014-in. Laminations Alternately Stacked	Equivalent Air Gap, In. (Total), with Careful Stacking
In groups of 1	0.0005
In groups of 4	0.001
In groups of 8	0.002
In groups of 12	0.003
In groups of 16	0.004
Butt stacking with zero gap	0.005

In grain-oriented steel cores the air gap may be large compared with l_c/μ_Δ, because of the high *incremental* permeability of these cores. When this is true, variations in μ do not affect the total effective magnetic path length or the inductance to substantial degree. Reactor properties may then be taken from Fig. 63.[1] To keep the reactor linear, it is necessary to limit the flux density. For grain-oriented silicon-steel cores, inductance is usually linear within 10 per cent if the d-c component of flux B_{dc} is limited to 12,000 gausses and the a-c component B_{ac} to 3,000 gausses.

Dotted lines in quadrant I are plots of turns vs. core area for a given wire size and for low-voltage coils, where insulation and margins are governed largely by mechanical considerations. Core numbers in Fig. 63 have the same dimensions and weight as in Table 6.

If the cores increased in each dimension by exactly the same amount, the lines in quadrant I would be straight. In actual cores, several factors cause the lines to be wavy:

1. Ratios of core window height to window width and core area deviate from constancy.
2. Coil margins increase stepwise.
3. Insulation thickness increases stepwise.

Instructions for Using Fig. 63.

1. Estimate core to be used.
2. Divide required inductance by area A_c of estimated core to obtain a value of L/sq in.
3. In quadrant II, locate intersection of L/sq in. and rated I_{dc}.
4. On this intersection, read total gap length l_g and number of turns N. Gap per leg $= l_g/2$.
5. Project intersection horizontally into quadrant I to intersect vertical line which corresponds to estimated core. This second intersection gives d-c resistance and wire size.

Example: Required: 15 henrys at I_{dc} = 50 ma.
Estimate core No. 1.
L/sq in. = 84.3, l_g = 0.015 in., N = 6,000, DCR = 800 ohms.
Wire size = No. 36.
(Example shown starting with small circle.)

A similar chart may be drawn for silicon-steel laminations, but to maintain linearity lower values of flux density should be used.

Equation (16) gives the inductance of a linear reactor with an air gap. It is assumed that 85 per cent of the core flux is confined to the cross section of core face adjoining the gap. The remaining 15 per cent of the core flux "fringes" or leaves the sides of the core, thus shunting the gap. Fringing flux *decreases* the total reluctance of the magnetic path and *increases* the inductance to a value greater than that calculated

[1] Lee, Reuben, Linear Reactor Chart, *Electronics*, March, 1955, p. 208.

from Eq. (16). Fringing flux is a larger percentage of the total for larger gaps. Very large gaps are sometimes broken up into several smaller ones to reduce fringing.

If it is again assumed that the air gap is large compared with l_c/μ, the reluctance of the iron can be neglected in comparison with that of the air gap. For a square stack of punchings, the increase of inductance due to fringing is

$$\frac{L'}{L} = \left(1 + \frac{2l_g}{\sqrt{A_c}} \log_\epsilon \frac{2S}{l_g}\right) \tag{17}$$

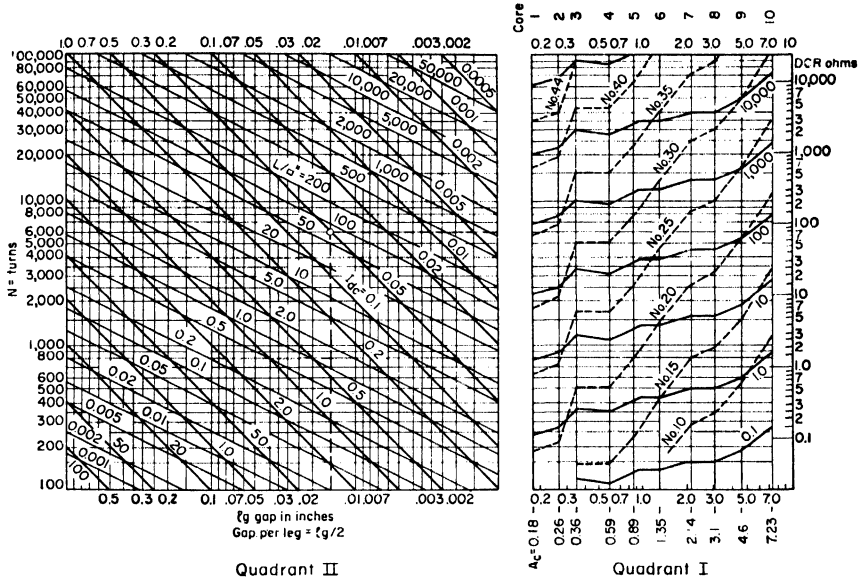
where S is the window length plus $l_g/2$.[1]


FIG. 63. Linear reactor design chart.

33. Saturable Reactors. The voltage induced in a winding usually far exceeds the resistance drop in that winding. In other words, winding open-circuit reactance usually is much greater than winding d-c resistance. Also a relatively small amount of d.c. flowing into the winding of a transformer, in the core of which there is no air gap, causes the core to saturate. Thus, the reactance of the transformer may be varied by a small amount of d-c power. Now, if one winding of a transformer is connected between an a-c supply and a load, the amount of power delivered to the load may be controlled by a small amount of d-c power flowing in another winding. Because of the fact that open-circuit reactance ordinarily exceeds d-c resistance, the possibility of power amplification is inherent in a transformer. When one winding of a transformer is used for d-c control power and another for a-c output power, the transformer is called a saturable reactor.

To keep the d-c source from being a short circuit to the a-c voltage in the power winding, common practice is to use two reactors, the d-c windings of one of which are reversed, while the a-c windings add normally. Connections of this sort are shown in Fig. 64*a*, with the a-c windings in series; it is possible to connect them in parallel as in Fig. 64*b* to allow more load current to flow at lower a-c voltage.

[1] Partridge, G. F., The Inductance of Iron-cored Coils Having an Air Gap, *Phil. Mag.*, **22**, 675 (7th Series), July-December, 1936.

When there is zero d.c. in the control windings of Fig. 64, both reactor impedances are large and prevent any load current except exciting current from flowing throughout the a-c voltage cycle. When d.c. is applied to the control windings, impedance remains large for the first part of a cycle, until saturation flux density is reached. Then reactor impedance is reduced and a large load current may flow. With grain-oriented core material, the change from high to low impedance is abrupt, and the load current wave form is as shown by i_L in Fig. 65*a*. Only the exciting current flows in the load during the interval 0 to θ_1. Then saturation is reached and load current suddenly rises to a large value. From θ_1 to π, i_L has sinusoidal shape. During the next half cycle, this load-current shape is repeated but in the reverse direction.
FIG. 64. (*a*) Series-connected and (*b*) parallel-connected saturable reactors.
FIG. 65. Saturable reactor currents with (*a*) high and (*b*) low control-circuit resistance.

For a 1:1 turns ratio in each reactor, current i_c in each control winding equals i_L minus the exciting current. In one reactor, because of the reverse connection, current i_c flows in the opposite direction. Total current in the control circuit is as shown by the lowest trace of Fig. 65*a*, the average value of which is the input direct current I_c. Thus load current contains fundamental and odd harmonics, whereas control current contains only even harmonics. If sufficient control current flows to saturate the cores over the full cycle, load current also flows over the full cycle and is sinusoidal in wave form. For turns ratios other than unity, load and control currents are inversely proportional to turns ratio.

In the foregoing it was assumed that control current was free to assume the shape shown in Fig. 65*a*. This is true on a 1:1 turns-ratio basis only if the control circuit impedance is small. If total control circuit resistance is denoted by R_C and load resistance by R_L, for $R_C \ll R_L$, load and control currents are sine waves, or portions

thereof. If the opposite is true, namely, $R_C \gg R_L$, control current wave shape is determined by R_C. For very large R_C, control current is continuous, and the current wave shapes approach those in Fig. 65*b*. In this figure, d-c source impedance is large, even harmonics cannot flow, magnetization is "constrained," load current is flat-topped, and voltage across the reactor is distorted considerably. This distortion can be overcome by the use of a capacitor across the control coils as shown dotted in Fig. 64. When the reactors are parallel-connected as in Fig. 64*b* even harmonics may flow in the load windings, and the capacitor is not needed.

Fig. 66. Windings and core flux paths in a saturable reactor.

Sometimes the two cores are combined into one, in the manner shown in Fig. 66. This is called a three-legged reactor, with one d-c coil and two a-c coils. Figure 66 shows the relative paths for the a-c and d-c fluxes. Equal turns in the a-c coils set up equal a-c magnetomotive forces which cancel in the center leg, and cause flux to flow as indicated by the solid line. No fundamental a-c voltage is induced in the d-c coil, but d-c flux flows in both outer legs as indicated by the dotted lines. A change of current in the d-c coil causes a change in total flux linking the a-c coils and hence a change of inductance. A-c coils may be connected in parallel instead of series, provided that equal turns in each coil and the flux polarity of Fig. 66 are maintained; for the same total number of turns the inductance is halved and the a.c. doubled. The middle core leg shunts the even harmonics of a-c flux.

Fig. 67. Magnetization curves for 4 per cent silicon steel.

It is only in grain-oriented core materials that the wave shapes of Fig. 65*a* are even approximated. In unoriented core steel, wave shape is much more rounded, and control current bears less resemblance to load current. Figures 67 and 68 indicate the contrast in saturation control afforded by unoriented silicon steel and oriented nickel steel. In grain-oriented steel cores there is an approximately linear relationship between d-c ampere-turns per inch and a-c ampere-turns per inch over a large range of

flux density. Moreover, the a-c NI/in. for a given d-c NI/in. changes only slightly with a-c flux density over this range. In Fig. 68, each of the lines for a given value of control magnetizing force is nearly vertical. For a given value of control NI/in., load current is almost independent of flux density and therefore of a-c supply voltage.
FIG. 68. Typical magnetization curves for 0.002-in. grain-oriented nickel-steel toroidal cores.

Grain-oriented nickel steel cores are wound of thin strip into toroids. The remainder of this section is based on the use of grain-oriented core steel.

If we choose three line voltages corresponding to flux densities within the linear portions of Fig. 68, and plot the d-c control vs. a-c load ampere-turns per inch, the curves of Fig. 69 result. If, instead of NI/in., average load current is plotted, Fig. 69 gives the transfer curves for a simple magnetic amplifier. The curves are symmetrical
FIG. 69. Simple magnetic amplifier transfer curves with line-voltage variations.

about zero ampere-turns. The difference between the transfer curve and a straight line indicates the degree of nonlinearity in the amplifier for any load current. With grain-oriented core material the a-c load current is nearly independent of supply voltage for a-c inductions less than saturation.

Because of the inductance of the reactor coils, when a change is made in the control winding d.c., load current does not change immediately to its final value. An interval of time, called *response time*, elapses between the change in control current and the establishment of a new steady value of load current. For series-connected reactors,

an average or equivalent control circuit inductance may be found from the relation

$$T_d = \frac{L_c}{R_c} = \frac{R_L}{4fR_c}\left(\frac{N_c}{N_L}\right)^2 \tag{18}$$

where T_d = time for load current increment to reach 63 per cent of final value
L_c = equivalent total control coil inductance, henrys
R_c = total control circuit resistance, ohms
R_L = load resistance
f = line frequency
N_c = turns in control winding
N_L = turns in load winding

For parallel-connected reactors the time of response is appreciably longer. If a rectifier is interposed between the reactor and load, it is possible to obtain sufficient power from the rectifier to supply most of the control power. If the control power from the rectifier furnishes the ampere-turns represented by the straight line in Fig. 69, the amplifier is said to have 100 per cent "feedback." It is then necessary for the control winding to supply only the amount represented by the horizontal difference between the transfer curve and the straight line. This greatly increases the amplification of a pair of reactors; response time increases, but gain per second increases, transfer curve is asymmetrical, and gain is more dependent on supply voltage than in simple magnetic amplifiers. These magnetic amplifiers form a separate subject, for which the reader is referred to the literature, which is extensive.[1]

34. Filter Capacitors. Filament-type rectifiers come up to operating temperature in a few seconds and begin supplying rectified voltage before indirectly heated cathode tubes (load) are warm enough to take their rated currents. Dry-contact rectifiers also operate quickly; the warm-up time is zero. Thus peak voltages are used in specifying filter-capacitor ratings. For example, the first capacitor should be rated to stand 1.41 times the rms transformer secondary voltage; for a 400-0-400-volt secondary the peak is 400 × 1.41 = 564 volts (half the secondary supplied peak voltage in a full-wave rectifier). The second and third filter capacitors also may receive practically full peak voltage when no load current is drawn. For some circuits, an appreciable percentage of the total load current flows in a voltage divider as a waste or "circulating" current. In this case, the second and third capacitor ratings can be proportionally lower by the amount of the voltage drop in the chokes or filter resistors.

While it is true that good filter capacitors will stand voltages greater than their d-c ratings, the regular practice of applying such higher voltages is seldom advisable from a life standpoint. Electrolytics, especially, are subject to rapid deterioration if worked above their ratings.

In general, the paper capacitor has no polarity and extremely low leakage current, changes little with wide temperature variations, is more expensive, weighs more, takes up more space for a given capacitance, and has long life. Paper capacitors are made for practically any high voltage, but seldom rated lower than 400 volts d.c. working.

Electrolytic capacitors are polarized, have appreciable leakage currents, somewhat restricted temperature ranges; single units are available for voltages up to 600 d.c. working, are relatively inexpensive, light in weight, and small in volume for a given capacitance. They have shorter life than paper capacitors. Reasonably sized electrolytics can be made with several thousand microfarads at such low working voltages as 15, 30, and 50.

The life and stability of an electrolytic capacitor are largely determined by the operating temperature of its electrolyte. The temperature depends on how much

[1] For example see Ramey, R. A., On the Control of Magnetic Amplifiers. *Trans. AIEE*, **70**, 2124, 1951. Miles, James G., Bibliography of Magnetic Devices and the Saturable Reactor Art, *Trans. AIEE*, **70**, 2104, 1951 (containing a list of 901 references). Storm, H. F., "Magnetic Amplifiers," Wiley, 1955, contains extensive bibliography.

heat is generated inside the capacitor and the rate at which heat is taken away by the surroundings. Electrolytic capacitors are normally rated for an ambient temperature of 60°C. Specially processed units can operate at 85°C. The low-temperature operating limit is seldom a problem for indoor use, but capacitors for use at temperatures as low as −40°C can be made with the effective rated capacitance as 40 per cent that at normal room temperature.

Typical specifications for electrolytic capacitors include rated capacitance and tolerance, operating frequency, rated voltage, normal operating voltage, peak operating voltage, operating temperature range (max and min), type of circuit used (full-wave, half-wave, doubler, etc.).

Paper filter capacitors are usually oil-filled or wax-impregnated. The selection of the proper oil or wax depends largely on the temperature range to be encountered, either in use or idle. Complete specification for a paper-dielectric capacitor requires: capacitance and tolerance; maximum instantaneous peak voltage; a-c ripple frequency; half-wave or full-wave; average ambient temperature; maximum and minimum temperature expected when not operating; special operating conditions such as high humidity, dusty location, high elevation.

High-voltage capacitors are immersed in oil, askarel, or other special insulating fluids. TV high-voltage dry-type ceramic capacitors rated up to 500 μμf, 30,000 volts, are available with +50 to −20 per cent standard tolerance. By-pass ceramic-disk capacitors are rated up to 0.02 μf at 500 volts and up to 100 μμf at 6,000 volts. Tantalum capacitors are useful for low voltages where maximum ratings of 300 μf at 6 volts or 25 μf at 125 volts are required. Both tantalum and ceramic-disk capacitors have large capacity tolerances and are especially suited to printed circuits and other applications in which small dimensions are necessary.

POWER-SUPPLY-VOLTAGE CONTROL

35. Control and Regulation. Power-supply voltage is varied to obtain suitable volume, brightness, or other output levels. This is accomplished by controlling the transformer primary voltage, or turns ratio, or secondary voltage, by variable autotransformers, tap switches, tubes, or magnetic amplifiers. Once the right voltage is established, it may be necessary to hold it constant in spite of line voltage or load changes. Constant d-c output requires some kind of regulator on most power systems. It is with this meaning of the word "regulation," as distinct from the no-load to full-load regulation with constant line voltage described in Sec. 18, that the following sections are concerned.
Fig. 70. Vacuum-tube voltage regulator.

36. Tube Regulators. In low-power applications vacuum-tube regulators are used. Output voltage is determined by a V-R cold-cathode tube used as a reference. A control tube is connected between rectifier output and load, with the grid responsive to changes in d-c output voltage. In this way, control-tube plate resistance is varied automatically to maintain constant output voltage.

Figure 70 is the diagram of such a regulator.[1] Here V_1 is the control tube, V_2 a voltage amplifier, and V_3 the V-R tube. When output voltage rises higher than the value for which the potentiometer is set, the potential difference between grid and cathode of V_2 increases. The increase of V_2-grid voltage causes more current to flow through R_1, an increase in the grid bias on V_1, an increase in V_1 plate resistance, and restoration of d-c

[1] Sulzer, P. G., Stable Electronic Voltage Regulator, *Electronics*, **23**, 162, December, 1950.

output voltage back to normal. Voltage stability of 0.1 per cent or better is achieved in this manner. Ripple is attenuated by this regulator to a degree comparable with output-voltage stability. Amplifier tubes are connected in cascade to obtain still closer regulation.

Control of large amounts of power is accomplished by thyratrons or ignitrons. These devices generally block a-c voltage applied to the anode during a nonconducting period of each cycle, and then suddenly permit current to flow during the remainder of the cycle or half cycle. Current wave form in the load is similar to that of i_c in Fig. 65, where nonconducting periods are 0 to θ_1 and π to θ_2. Hence, ripple in the load increases as θ_1 increases.

An electronic voltage reference and thyratrons are used together in the circuit of Fig. 71 to form an exciter field regulator. X_1 and X_2 are saturable reactors. Regulator tube V_1
FIG. 71. Thyratron control of generator excitation.

maintains V_2 grid at constant potential. An increase of a-c voltage on T_2 and T_1 causes the cathode potential of V_2 to increase, and reduces its plate current. This reduces the saturation of X_1 and X_2, which in turn shifts the grid-cathode a-c potentials on V_3 and V_4 and thus reduces the generator field excitation. With restoration of normal a-c supply voltage (preset by R_3) the regulating action ceases.

37. Magnetic Regulators.[1] Magnetic amplifiers may be used in place of thyratrons for controlling voltage in the circuit of Fig. 71, but diodes are necessary for d-c output. If these diodes are used in self-saturating circuits the amplifying, and hence the regulating, action is increased. Magnetic references have been developed to replace the V-R tube with gains in reliability and ruggedness. These magnetic devices are frequency-sensitive unless special circuits are used.

A magnetic regulator for controlling a-c line voltage is shown in Fig. 72. This is a resonant-reactor voltage regulator. L_1 is linear. L_2 and C_2 are nearly parallel-resonant at the supply-line frequency and rated voltage. Output current flows through the secondary of L_1 which is of such polarity as to better maintain rated voltage. L_2 is partially saturated at this voltage. If line voltage falls below rated value, less current is drawn by L_2, and the

[1] See Evans, W. G., Saturating Transformer Reference Circuit, *Trans. AIEE*, **74**, 610, 1955. Anderson, F. W., "A Line Voltage Regulator Having Magnetic Amplifier Control," AIEE Paper 56-227.

L_2C_2 combination becomes more capacitive. This capacitive current, drawn through L_1, raises the output voltage. Conversely, if line voltage rises above rated value, the L_2C_2 combination becomes less capacitive and the output voltage falls below the line value. This regulator is practical for ratings up to 10 kva. Output voltage variations of ±1 per
FIG. 72. Resonant-circuit voltage regulator.

cent are obtained with ±10 per cent line-voltage variations in this manner, and with load changes from zero to full load. Constant supply frequency is a condition for resonance at rated voltage; with the good frequency control of modern power systems this condition is generally fulfilled.

CHAPTER 18

RADIO TRANSMITTERS

BY WARREN B. BRUENE[1]

The equipment used for converting electrical power received from a primary source into r-f energy modulated with a signal for transmission by means of electromagnetic waves through space is known as a radio transmitter. Transmitters are usually classified according to the type of signal they transmit, the portion of the spectrum in which they operate, and, frequently, the service for which they are used, for example, medium-frequency broadcast transmitters, high-frequency radiotelegraph transmitters, v-h-f scatter transmitters, v-h-f air-borne communication transmitters, u-h-f television transmitters, etc. (for frequencies, see Chap. 1, Table 1). Transmitters are required to operate in frequency bands or channels assigned by a frequency-allocating authority (FCC) which must consider the service to be performed, the characteristic of the propagation medium, the state of the art, etc. Generally, the low and medium frequencies up through the 540- to 1,600-kc broadcast band depend upon ground-wave propagation which gives reliable continuous area coverage, and the distance depends largely upon the r-f power radiated. Transmitter powers from 250 watts to 500 kw are used in this frequency range. Services which use this frequency range are a-m radiobroadcasting, maritime navigation, and communication in the arctic auroral regions. In the h-f region, 3 to 30 Mc, reflections from the ionosphere cause radio signals to travel long distances with relatively low attenuation. Transmitters ranging from a few watts to 200 kw are used, but powers of 100 watts to 5 kw are most common. Directional antennas providing gains of up to 20 db are employed frequently. The higher-powered transmitters are usually used for multichannel circuits and for short-wave broadcasting to provide adequate reception with simple receivers and poor antennas. The demand for frequency assignments in this part of the spectrum which is useful for long-distance transmission is very great. Those services able to use other frequencies are required to do so. Services such as long-distance communication with aircraft, ships at sea, some point-to-point services which must have independent circuits or which are inaccessible to other means, short-wave broadcast, and the vast military requirements for an independent flexible mobile system are the principal users of the high frequencies. The frequencies in the 30- to 50-Mc region are beyond the frequencies which are reflected by the ionosphere and have been used largely for communication with mobile stations. During the last few years ionospheric scatter propagation has been found useful and is being exploited for reliable continuous-duty circuits over distances of 350 to 1,200 miles. The 30- to 50-Mc region is optimum for this form of propagation. High power on the order of 20 to 50 kw and high-gain antennas are essential. Above 54 Mc are 6-Mc-wide television channels. Power outputs of 5 to 50 kw are usually used with high-gain antennas to achieve effective radiated powers up to 1,000 kw. A great many services use the frequencies above 100 Mc. In general, they use low-power transmitters for general coverage to and from local fixed or mobile stations, and for various navigation services. Microwave stations usually use very low transmitter powers with very-high-gain antennas. An exception is circuits which use tropospheric scatter propagation. These frequently use powers of 1 to 10 kw with high-gain antennas for transmission over distances up to about 350 miles.

[1] Collins Radio Company, Cedar Rapids, Iowa.

The uses and demands for more communications circuits have spurred development of equipment to make use of higher and higher frequencies and also to make better use of the frequency spectrum available.

Many variations of the basic types of modulation are used, and more are continually being developed. Each has its advantages and disadvantages and general field of usefulness. The channel band width required depends upon the type of modulation (a.m., f.m., pulse, etc.), carrier-frequency stability, and the selectivity of receiving equipment. More and more channels are becoming available as the state of the art in each of these fields advances. At present, it appears that single side band (SSB) makes the most efficient use of spectrum space when transmitting a voice signal, and radiotelegraph systems using nearly ideal code modulation and detection[1] are best in this field. Both require very high frequency stability at both transmitter and receiver and hence are restricted to frequencies below 50 Mc until the art of obtaining higher frequency stability improves. Above 50 Mc, frequency modulation is usually used which obtains a signal-to-noise advantage by using more spectrum space. It also has the advantage of transmitter simplicity, which is important in mobile equipment. Another advantage is relative ease of obtaining a wide audio band width for high fidelity. In the microwave region various types of pulse modulation are used to realize signal-to-noise advantages and make the best use of this part of the frequency spectrum.

ELEMENTS OF TRANSMITTERS

Each stage, which includes the circuit about a vacuum tube, is usually described by the function it performs. In addition, various sections of a transmitter are usually referred to according to their function. The more important ones, which are generally similar in many types of transmitters, are exciters, r-f power amplifiers, audio amplifiers, modulators, power supplies, control circuits, and cooling systems.
Fig. 1. Block diagram of typical exciter.

1. Exciters. The exciter is usually considered that part of the transmitter which generates the transmitter output frequency and raises it to a power level suitable for exciting the r-f power-amplifier stages. There is a very wide range of exciter requirements and functions; frequently that part of the transmitter which is mounted physically on a single chassis or the transmitter unit which most nearly meets the above definition is called the exciter. The block diagram shown in Fig. 1 illustrates how some of the circuits found in exciters are used.

2. Oscillators. Oscillators provide the source from which the carrier frequency is generated. They must provide r-f voltage precisely at the desired frequency, with a high order of frequency stability and free of hum or noise modulation. The FCC specifies certain limits within which the transmitter frequency must be maintained. For example, m-f transmitters may be allowed a range of ±20 cps from the assigned frequency, while h-f transmitters may be required to be within 0.005 per cent of carrier frequency, which represents ±500 cps at 10 Mc. The limits are established to be about as high as the state of the art permits in a practical economical transmitter design. Limiting the frequency tolerance permits transmitter channels to be assigned closer together and allows use of greater selectivity in the receiver. Some communications systems, such as SSB, require frequency stabilities much greater than this unless automatic frequency control (AFC) is used in the receiver.

There are many factors which affect the frequency stability of an oscillator. Some

[1] Doelz, M. L., Predicted Wave Radio Teleprinter, *Electronics*, December, 1954, p. 166.

of the more important are d-c plate voltage, temperature, humidity, load impedance, and mechanical rigidity. Frequency variations due to varying d-c plate voltage can be minimized by providing a very well regulated and well filtered power supply. Temperature effects are reduced by placing the oscillator, or at least its temperature-sensitive frequency-determining components, in a temperature-controlled oven. Hermetic sealing provides a means of overcoming the frequency variations due to changes in relative humidity of the surrounding air. A buffer amplifier stage will isolate the effects of a varying load impedance from the oscillator. Shielding is also usually desired or required to keep r-f energy from a power-amplifier stage from coupling into the oscillator and affecting its frequency. This shows up mostly when the power amplifier is tuned, keyed, or modulated. The oscillators in most modern transmitters use small receiving-type tubes operating with only a few volts across the oscillating circuit. This demands a high order of circuit isolation, particularly when the oscillator is used in a high-powered transmitter.
FIG. 2. Popular high-frequency crystal oscillator circuit.

Another effective means of reducing the effects of a small amount of coupling to a power stage is to operate the oscillator on a different frequency than the power stage. In h-f transmitters the oscillator is commonly operated on a subharmonic of the carrier frequency, and frequency multipliers are used to generate the carrier frequency from the oscillator frequency.

Crystal oscillators are normally used because they are capable of much higher frequency stabilities than conventional tuned oscillators. When several frequencies are required, a switch is used to select the appropriate crystal. The quartz-crystal plates are usually mounted in a holder of some type with the frequency marked on it. Oscillation on this exact frequency is not guaranteed in any oscillator circuit other than the standard one in which it was calibrated. The circuit capacitance across the crystal is the important factor. One widely used standard value of oscillator-circuit capacitance is 30 $\mu\mu$f, although other values ranging from half to twice this value have been used. A small trimmer capacitor is frequently placed across the crystal to adjust the total circuit capacitance to the proper value or to trim the crystal into the desired frequency of oscillation. A popular crystal oscillator for transmitters is shown in Fig. 2. It has the advantages that no tuned circuits are required and the output is "electron-coupled" to the oscillating circuit for reduced load-variation effect. The preferred crystal-frequency range for this circuit is 2 to 8 Mc but it may be used well beyond this range.

High-stability operation is more difficult to achieve in tunable oscillators but in some cases their use is necessary. One type of highly developed variable-frequency oscillator (VFO) is shown in Fig. 3. A powdered-iron or ferrite core is moved in and out of the coil to vary the tuning. The coil is wound with a variable pitch so the calibration curve of shaft turns vs. frequency is a straight line and each turn produces an integral frequency range, such as 50 or 100 kc. A final refinement in tuning

linearity is made during the final calibrating procedure during manufacture by means of the cam-type frequency corrector. Each oscillator is individually temperature-compensated to reduce temperature effects and hermetically sealed to minimize effects of relative humidity. One oscillator can tune over a frequency range of a full octave. Best frequency stability can be achieved with this type of oscillator within the frequency range of 450 to 4,000 kc.

3. Frequency Synthesizers. Synthesizer units have been built which can provide fixed frequencies at 1-kc intervals across part or all of the h-f spectrum. A stable crystal oscillator oscillating at 100 kc or at 1,000 kc, for example, is the prime frequency
FIG. 3. Collins variable-frequency oscillator.

source from which any of the output frequencies are generated. This is accomplished by using frequency dividers, frequency multipliers, and mixers for addition and subtraction of various selected harmonics and subharmonics of the input frequency. The output frequency has the same frequency stability in per cent as the input frequency because it is derived completely from it. Sometimes the output of a VFO is added to the basic synthesizer circuit to provide interpolation between the fixed output frequencies in such a manner that continuous frequency coverage is achieved with the stability of the VFO contributing only a small amount to the synthesizer output-frequency stability.

Frequency synthesizers, in general, have two serious deficiencies for use as a transmitter carrier-frequency source. One is that it is almost impossible to keep all undesired output frequencies at a satisfactorily low level. The second is that the frequency dividers usually contain an undesirable amount of output-frequency jitter or noise.

4. Stabilized Master Oscillator. A means of overcoming these deficiencies is by use of a stabilized-master-oscillator circuit. The output frequency is derived from a stable master VFO which is further stabilized by trimming its frequency exactly to the desired output frequency by a frequency synthesizer and an a-f-c circuit. Some circuits provide a phase lock of the VFO frequency to the synthesizer output frequency. The stabilized-master-oscillator (SMO) output then has the same frequency stability

as the synthesizer-frequency source, which may be as high as 1 cps at 10 Mc. Figure 4 shows a block diagram of the principal sections of an SMO. The synthesizer may have two or three frequency-setting knobs, although late models show the output frequency directly in kilocycles. The synthesizer controls are coupled to the VFO also, using differential gears so that it is always tuned to be well within the pull-in range of the a-f-c circuit.

FIG. 4. Stabilized-master-oscillator circuit.

5. Frequency Multipliers. Frequency multipliers are used to keep the oscillator frequency off the carrier frequency, to reduce buffer isolation and shielding requirements, and to allow use of an oscillator with a limited frequency range in a wide-range transmitter. For example, a 2- to 4-Mc oscillator can be used with a 4- to 32-Mc transmitter by using frequency multiplications of 2, 4, and 8. This can be accomplished by using three cascaded doubler stages or a quadrupler stage followed by a doubler stage.

R-f frequency-multiplier stages are very similar to class C r-f amplifier stages except that the plate circuit is tuned to select the desired harmonic. The tube is biased well beyond cutoff and a large r-f grid voltage is used to obtain a short angle of plate-current flow which has high harmonic content. About 50 per cent plate efficiency can be realized from a frequency doubler. The efficiency of triplers is somewhat less and the output obtainable from multipliers drops rapidly with higher orders of multiplication.

FIG. 5. Spectrum of frequency-multiplier plate current.

The plate current of frequency multipliers is rich with harmonics, as shown in Fig. 5. The tuned circuits following the multiplier tube must select the desired frequency component and reject others of higher and lower frequencies to a satisfactory degree. This is another reason for using low orders of frequency multiplica-
FIG. 6. Multipliers for reduced undesired output.

tion since a tank circuit can better reject frequencies farther removed percentagewise from the desired frequency. It should be recognized that undesired output from the transmitter is possible at any harmonic of the oscillator regardless of the number of multiplier stages or their order of multiplication. Push-push doubler and push-pull
FIG. 7. Typical mixer circuit.

tripler circuits are frequently used to balance out the odd-order and even-order components in their outputs, respectively. Figure 6 shows typical circuits. Cascaded push-pull frequency triplers are commonly used in v-h-f and u-h-f transmitters where high orders of frequency multiplication are required. One example is in f-m broadcast-transmitter exciters.

6. Mixer Exciters. Mixer exciters can raise the frequency of an input signal without changing it in any other way. The output frequency is obtained by addition or subtraction of two frequencies instead of by multiplication, as shown in Fig. 7. Two principal applications of this circuit have been in frequency-shift keyer units and

Ratio of $\frac{A}{B}$ or $\frac{a}{b}$		Order						
		1	2	3	4	5	6	7
0	0	B b	$B \pm A$ $b \pm a$	$B \pm 2A$ $b \pm 2a$	$B \pm 3A$ $b \pm 3a$	$B \pm 4A$ $b \pm 4a$	$B \pm 5A$ $b \pm 5a$	$B \pm 6A$ $b \pm 6a$

Output frequency = $B + A$ or $b - a$.

FIG. 8. Mixer-frequency chart.

in SSB exciters. In each case, the signal is generated in the 100- to 500-kc region and converted to a higher frequency. Two conversion frequencies are usually used to convert the signal to the final carrier frequency in SSB exciters.

A great deal of care must be exercised in the choice of conversion frequencies to avoid undesired frequencies in the exciter output. For example, if the desired output is close to the third harmonic of one of the input frequencies, both will appear in the output and cannot be separated by tuned circuits. These undesired frequencies consist of all the harmonics of the input frequencies plus all the possible sum and difference combinations of all harmonics. The table and chart in Fig. 8 show all mixer products up to seventh order. The upper-case letters indicate that the desired output is the sum of the two input frequencies and the lower-case letters indicate that it is the difference. The amplitude of these various products varies greatly. In general, all second-, third-, and fourth-order products and the stronger fifth- and sixth-order products should be avoided by selecting conversion frequencies so these products can be removed from the desired output frequency with a practical number of tuned circuits. The selectivity of tuned circuits depends upon their circuit Q, source impedance, and coefficient of coupling. In some cases the tuning or tracking error must also be considered. Figure 9 can be used to estimate the attenuation of an undesired signal located a distance from the desired frequency using a single resonant circuit. The value of Q used must be the effective circuit Q, including all loading and source impedance effects and not just the Q of the coil alone.

Balanced-modulator mixers are sometimes used which balance out some undesired products resulting in from 20- up to 50-db improvement if balancing adjustments are provided. Figure 10 shows one type of balanced modulator which balances out the conversion-frequency input and all odd harmonics of it.
FIG. 8. Mixer-frequency chart. (*Continued.*)
FIG. 9. Generalized selectivity curve, single-tuned circuit.

7. Single-side-band Exciter. In most commercial single-side-band transmitters the SSB signal is generated in an SSB generator at a frequency in the range of 100 to 500 kc. This is raised to carrier frequency by the SSB exciter. Some exciters for h-f transmitters operating in the 4.0- to 30-Mc range convert the SSB generator output to a fixed intermediate frequency of about 3 Mc, as shown in Fig. 11. The signal is heavily filtered at this frequency to remove all undesired mixing products. It is then converted to the desired carrier frequency in one more conversion.

FIG. 10. Balanced modulator.

A frequency scheme suitable for covering the range of 1.7 to 30 Mc is shown in Fig. 12. Two mixing steps are used. It is noted that the two conversion frequencies are obtained from a single oscillator. The first conversion frequency is that of the oscillator and the second is a harmonic of it. This particular frequency scheme has many
FIG. 11. SSB exciter for 4- to 30-Mc output.
FIG. 12. SSB exciter for 1.7 to 30 Mc.

advantages and was chosen as a good compromise for commercial general-coverage h-f transmitters. Only one stable h-f oscillator is required, and the carrier frequency is easily determined because it is the first, second, fourth, or eighth harmonic of the oscillator less the 300-kc input frequency.

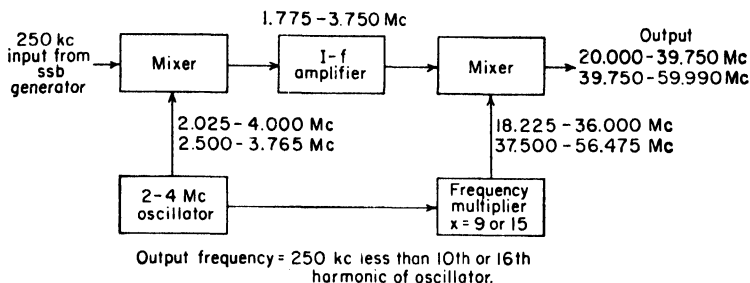
Using two variable conversion frequencies allows the large frequency coverage with a minimum of undesired mixing products near the output frequency.


FIG. 13. SSB exciter for 20 to 60 Mc.

An exciter for use in the 20- to 60-Mc range is shown in Fig. 13.

The 250-kc SSB generator output is raised to the desired frequency range in two frequency conversions. Several tuned circuits are required following each conversion to reject the undesired conversion products. The conversion frequencies are synthesized from one very stable standard crystal oscillator to achieve the frequency stability necessary for SSB in this frequency range.

R-F POWER AMPLIFIERS

Tuned circuits are generally used in the input and output circuits of r-f power amplifiers. Electron tubes, which are the power-generating elements, inherently have a significant amount of input and output capacitance. The tubes cannot work efficiently when shunted by low values of capacitive reactance, so that it is necessary to remove this shunting effect. Tuned circuits are used for this purpose. In addition, they are used to provide impedance matching of the tube to its load and also to provide a continuous sine-wave output from amplifiers with tubes which deliver power during only part of the r-f cycle.

FIG. 14. Typical r-f amplifier.

8. Classification. Radio-frequency amplifiers are divided into classes A, B, and C according to the angle of plate-current flow. (Angle refers to the number of degrees of current flow during an r-f cycle of 360 deg.) Class A amplifiers have a continuous plate-current flow and operate over a small portion of the tube's plate-current range as shown in Fig. 15*A*. This class of amplifier is used for amplification of small signals and in linear amplifiers for low distortion. Its efficiency in converting d-c plate-power input to r-f power output is quite low, but this is seldom of major importance where small signals are amplified. Class B amplifiers have their grids biased to near plate-current cutoff, so that plate current flows for approximately 180 deg of the r-f cycle. Amplifiers operated with appreciably more than 180 deg of plate-current flow but less than 360 deg are called class AB amplifiers. Class AB and class B r-f operation is used in linear amplifiers where higher efficiency and maximum output power with low distortion are required. Plate efficiency is in the range of 50 to 75 per cent, depending upon the tube and its operating condition. Typical uses are amplifiers in low-level a-m transmitters and in SSB transmitters. When the grid is biased well

beyond cutoff so that plate current is less than 180 deg the stage is called a class C amplifier. Its principal advantage is high plate efficiency, 65 to 85 per cent. They are usually operated with the r-f plate voltage in the region of saturation so that the r-f output voltage is very closely dependent upon the d-c plate voltage. Varying the d-c supply voltage to the tube at an audio rate by means of a modulator produces an a-m r-f output voltage. Class C amplifiers are used in the power-amplifier stages of radiotelegraph transmitters for c-w and frequency-shift-keyed output, in phase- and frequency-modulated transmitters, and in a-m transmitters which employ high-level plate modulation.

A subscript number is frequently added to the letters indicating the class of operation to indicate whether or not the tube is operated in the positive grid region over
FIG. 15. Plate-current flow in class A, B, and C amplifiers.

part of the cycle. For example, class AB_1 indicates that the grid never goes positive and that no grid current is drawn, while AB_2 indicates that the grid does go positive and that some grid current flows. Because class A amplifiers nearly always operate without grid current, and class C amplifiers nearly always operate with grid current, and because this is assumed unless otherwise designated, the subscripts are seldom used with class A or class C amplifiers.

9. Tube Types. Grid-controlled transmitting-type tubes are used at frequencies up to approximately 1,000 Mc. Klystron-type tubes are popular r-f power amplifiers in the 200- to 3,000-Mc region. Starting in this frequency range and going higher, magnetrons, traveling-wave tubes, etc., are used. Cavity resonators or special resonating circuits are usually required in tubes other than the grid-controlled types. They are usually built in or well defined by the tube manufacturer.

The design of transmitting-type tubes has been undergoing a continual evolution. Thoriated tungsten has almost completely replaced pure tungsten for filament material in high-powered tubes, resulting in a very substantial saving in filament power. The television industry's demand for power tubes in the v-h-f and u-h-f range has resulted in many new developments. In addition to good performance, the demand for reliability and long tube life is increasing. The trend is toward small compact tube design, which is necessary to reach the higher frequencies. External-anode types are increasing since they are more compact, have lower output lead inductance, and allow more efficient cooling. Ceramic insulation for the tube seals, instead of glass, is being used more because it is adaptable to precision tube manufacture, higher-temperature operation, better tube degassing in manufacture, and more rugged construction. Cathode emitters are starting to replace thoriated-tungsten filaments in tubes up to the 1-kw power level. Their high emission capability permits a low-impedance and high-transconductance design which is particularly useful in broad-band circuits. These features, plus the manufacturing precision required in producing tubes with the

small element spacings required for high transconductance and u-h-f operation in general, increase tube cost. The transmitter-design engineer should carefully weigh the factors of reliability, performance, and cost, when selecting a tube for a given application.

Good reliable triode-type tubes are available for nearly every application and power level up into the h-f ranges. More tetrodes and pentodes are being developed to meet the demands for higher power gain and reduction or elimination of the neutralizing requirement. One disadvantage is that screen power must be supplied. Transmitters up to the 50-kw power level now frequently use tetrodes.

10. Calculation of Operating Conditions. The operating conditions of an r-f amplifier tube can be computed rather accurately using Chaffee's method of analysis.[1] The 11-point analysis is suggested because it gives adequate accuracy for almost all engineering purposes and little time is saved by using fewer points. Figure 16 illustrates the principle.[2] A set of constant-current characteristic curves for the tube is required, and sine-wave voltages on the grid and plate elements are assumed. This results in a straight load line on these curves, provided the plate circuit is tuned to resonance (unity power factor). Values are selected for the d-c plate voltage and grid-bias voltage. An operating load line A, Q, A' is chosen, and values of current are read at 15-deg intervals along the load line. These are used in the following equation to compute the d-c component I_{av}.*
FIG. 16. Graphical-analysis principle.

$$I_{av} = \frac{1}{12}\left[\frac{A}{2} + B + C + D + E + F + Q + F' + E' + D' + C' + B' + \frac{A'}{2}\right] \quad (1)$$

$$I_1 = \frac{1}{12}[(A - A') + 1.93(B - B') + 1.73(C - C') + 1.41(D - D') + (E - E') + 0.52(F - F')] \quad (2)$$

By taking readings of plate, grid, and screen current at the 15-deg points along the load line the d-c and peak a-c components of current can be computed for each element.

* Subscripts 1 indicate the fundamental component of current or voltage.

These values are then used in the following equations to determine the operating condition rather completely.

$$I_B = I_{p_{av}} \text{ d-c plate current} \tag{3}$$
$$P_{in} = E_B I_B = \text{plate input, watts} \tag{4}$$
$$P_o = \frac{I_{p_1} e_p}{2} = \text{output, watts} \tag{5}$$
$$\text{Eff} = \frac{P_o}{P_{in}} 100 = \% \text{ plate efficiency} \tag{6}$$
$$P_d = P_{in} - P_o = \text{plate dissipation} \tag{7}$$
$$I_{g_{av}} = \text{d-c grid current} \tag{8}$$
$$P_{dr} = \frac{I_{g_1} e_g}{2} = \text{grid driving power, watts} \tag{9}$$
$$P_c = I_{g_{av}} E_c = \text{drive power consumed by bias supply} \tag{10}$$
$$P_{gd} = P_{dr} - P_c = \text{grid dissipation, watts} \tag{11}$$
$$I_{s_{av}} = \text{d-c screen current} \tag{12}$$
$$P_{sd} = I_{s_{av}} E_s = \text{screen dissipation, watts} \tag{13}$$
$$R_L = \frac{e_p}{I_{p_1}} = \text{r-f load resistance} \tag{14}$$

These equations apply to conventional grid-driven circuits. The second and third harmonic components of current may be computed using the following equations.

$$I_2 = \tfrac{1}{12}[(A + A' + C + C' - E - E') + 1.93(B + B' - F - F') - Q] \tag{15}$$
$$I_3 = \tfrac{1}{12}[(A - A') + 1.41(B + D' + F' - B' - D - F) - 2(E - E')] \tag{16}$$

These are used for doubler and tripler computations. Harmonic currents flowing in the plate-tank capacitor, by-pass capacitors, and parasitic suppressors can also be estimated using these equations.

The grid driving power is almost invariably higher than anticipated from the above calculation. Allowance must be made for the grid-tank-circuit losses. In addition, starting in the h-f range, some driving power is fed through the tube due to filament or cathode lead inductance. This includes the internal tube leads, socket, and filament or cathode by-pass capacitors and their leads. This inductance is illustrated in Fig. 17 and the fed-through power can be estimated by the equation
Fig. 17. Filament-lead inductance which causes feed-through power.

$$P_{ft} = \frac{\omega^2 L_k C_{gk} e_g I_{p1}}{2} = \frac{X_k e_g I_{p1}}{2X_{C_{gk}}} \tag{17}$$

The cathode is driven by a voltage equal to the capacitive current flowing from grid to cathode multiplied by the cathode lead reactance. The driving power is this voltage multiplied by the fundamental component of plate current. This increases as the square of frequency and is one reason the older-type tubes with long filament leads became very hard to drive in the upper h-f region. This term can be reduced to zero by choosing a value of filament by-pass capacitor that will series-resonate the total lead inductance.

A net capacitive reactance in the cathode circuit causes plate power to be fed back into the grid circuit, causing a small amount of regeneration.

11. Cathode-driven R-f Amplifier Calculations. Triodes (and occasionally tetrodes) frequently are used in cathode-driven (grounded-grid) circuits as shown in Fig. 18. This circuit has the advantage that neutralization is seldom required because the grid is an effective shield between plate and cathode. The small values of plate-to-cathode capacitance have very little effect on the input signal because the

input impedance is usually only a few hundred ohms. Another advantage is that the minimum circuit input and output capacitance is lower than that of grid-driven triode circuits using broad-band neutralization.

Cathode-driven (or grounded-grid) amplifiers operate a little differently than conventional grid-driven amplifiers. This discussion will cover tetrode tubes, but the considerations for triodes are identical except that operations relating to the screen are omitted.

The calculations are minimized if a set of constant-current curves, which refers all voltages to the No. 1 grid, is available. Frequently they may be obtained from the tube manufacturer if they do not appear on the regular data sheet. The method of using conventional curves for cathode-driven service will be discussed in a later paragraph.
FIG. 18. Cathode-driven power amplifier.
FIG. 19. Load line on constant-current curves for cathode-drive operation.

To calculate the operating conditions, draw a selected load line on the curves for cathode-driven service. Remember that all voltages are referred to the No. 1 grid, but the actual d-c supply voltages normally are measured from the cathode. In practice, the cathode and the negative side of the d-c plate and screen supplies are at d-c ground potential. The point Q on the load line must be at a plate-to-grid No. 1 voltage on the curve, and this is the sum of the d-c plate voltage and d-c grid-bias voltage. For example, 3,000 volts of E_B and 100 volts of E_C gives 3,100 volts of plate-to-grid No. 1 voltage on the curves. The other coordinate of Q is at a cathode-to-grid No. 1 voltage equal to the grid-bias voltage but of opposite sign. The plate-current pulses occur when the cathode is driven in the negative direction. A typical load line on a set of curves is shown in Fig. 19 for class B operation. The d-c and fundamental a-c components are calculated using the method explained in the previous section.

The operating conditions are then calculated as follows:

D-c plate input

$$P_{\text{in}} = E_B I_{p_{\text{av}}} \tag{18}$$

Note that E_B is the d-c plate voltage from plate to cathode and not plate to grid No. 1.

R-f power output

$$P_o = \frac{e_p I_{p_1}}{2} \quad \text{watts} \tag{19}$$

Fed-through power

$$P_{ft} = \frac{e_k I_{p_1}}{2} \quad \text{watts} \tag{20}$$

Plate dissipation

$$P_d = P_{\text{in}} - (P_o - P_{ft}) \tag{21}$$

Driving power

This is composed of three components: the fed-through power, the grid-driving power, and the screen-grid-driving power.

$$P_{dr} = P_{ft} + P_g + P_s = \frac{e_k I_{p_1}}{2} + \frac{e_k I_{g_1}}{2} + \frac{e_k I_{s_1}}{2} \quad (22)$$

Grid dissipation

$$P_{gd} = \frac{I_{g_1} e_k}{2} - I_{g_{av}} E_c \quad (23)$$

Screen dissipation

$$P_{sd} = \frac{I_{s_1} e_k}{2} - I_{g_{av}} E_s \quad (24)$$

Input impedance

$$R_{in} = \frac{e_k}{I_{p_1} + I_{g_1} + I_{s_1}} \quad (25)$$

This varies a little with signal level in a class AB linear amplifier because the grid and screen currents do not vary linearly. At very low signal levels, the grid and screen currents are nearly always zero. In most SSB applications the cathode input impedance is very nearly that due to the fed-through power alone.

Other unknowns of interest may be calculated as discussed in the previous section.

Conventional constant-current curves for grid-driven operation can be used readily for triode cathode-driven amplifiers. A load line is selected as for grid-driven service and all calculations are made. The fed-through power must be added to the power output of the tube to obtain the total power output. Other than this, all the appropriate previous equations apply.

Accurate calculations cannot be made easily for tetrodes using these curves because the screen-to-cathode voltage varies over the cycle and the curves represent only the condition when the screen-to-cathode voltage is fixed. However, reasonably good estimates of power output and fed-through power can be made if all pertinent considerations are kept in mind.

Cathode-driven amplifiers have relatively low gain because of the large amount of fed-through power. When such a stage is plate-modulated, the driver stage must also be modulated so that the fed-through power will be modulated.

TUNED R-F COUPLING CIRCUITS

12. Tank-circuit Considerations. Resonant tank circuits are used in r-f power amplifiers to remove the effects of tube and circuit stray capacitances so that a resistive load can be presented to the tube plate, to maintain sine-wave r-f voltages, to provide a return path for harmonic components of grid and plate current, for selectivity to attenuate harmonic and other undesired frequencies, and for impedance matching. The data sheets for most tetrodes and pentodes list the tube input and output capacitances. Triode-tube data sheets usually merely list the interelectrode capacitances so that the input and output circuit capacitance, including that due to the neutralizing circuit, must be calculated as shown in Secs. 23 to 26. The tube input and output capacitances in cathode-driven operation are equal to the grid-to-cathode and the grid-to-plate capacitances, respectively. To the basic tube and neutralizing-circuit capacitance will be added socket capacitance and the various stray capacitances of leads and associated circuit components. The tuned circuits must be designed to resonate with these fixed values of circuit capacitance across them.

The design of class A voltage amplifiers for transmitters is very similar to that of receiver amplifiers. The tube type and operating condition chosen must be appropriate for the voltage output and gain desired. Tetrodes and pentodes are nearly always

used because they yield a higher gain and need a minimum amount of neutralizing. Their gain can be estimated by using the equation

$$G = g_m R_L \quad \text{or} \quad g_m Q X \tag{26}$$

if g_m at the desired operating d-c grid and plate voltage is known. The value of g_m given on transmitting-tube data sheets is usually measured at some other operating point which is convenient for measurement, so that it is necessary to estimate the g_m in the region of interest from the tube-characteristic curves. Very high voltage gains are theoretically possible when a high-Q tank coil is used in a low-capacitance tank circuit, but circuit stability places a limit on usable gain. The effects of a small amount of grid-to-plate capacitance and stray coupling between the grid and plate circuits increase with the amount of gain used. For high gain, a well-screened tube
FIG. 20. Essential tank-circuit elements.

with low grid-to-plate capacitance and low-inductance leads along with high g_m should be chosen. Neutralization and good shielding are desirable or necessary in the h-f region and above. The gain of an amplifier can be reduced by loading the output circuit with resistance. Fixed-resistance loading is also used frequently to keep the amplifier gain more uniform when tuning over a band of frequencies by swamping the effect of a varying QX.

It is necessary to maintain a substantial amount of stored energy in the plate tank circuit of class B and class C r-f power amplifiers to maintain approximately a sine-wave r-f voltage. The ratio of stored energy to the energy passing into and out of the circuit during one cycle is expressed as Q. The stored energy in that part of the tuned circuits directly connected to the tube is most important, and a capacitive reactance across the tube elements is desirable for a harmonic-current return path, so that the plate tank circuit Q is often expressed as the ratio of plate load resistance to the shunting-tank capacitor reactance.

$$Q = \frac{R_L}{X_c} \tag{27}$$

Preferred values of Q are between 8 and 20. Lower Q is sometimes used at frequencies below 1 Mc to maintain an adequate band width. Qs as low as 3 in push-pull amplifiers have been used in the 250- to 500-kc region. Care must be used in designing and tuning these circuits because the tube plate efficiency may be impaired. The d-c plate-current dip occurs at the maximum impedance point, which does not necessarily coincide with the unity-power-factor point. This is more noticeable when the element coupled to the load (for example, the tank coil) is tuned instead of a tank capacitor which carries only reactive current.

It is also desirable to maintain an adequate Q in the grid circuit, and a capacitive return from grid to cathode for the grid harmonic currents of class B and C power-amplifier tubes should be provided. Examples are shown in Fig. 20. A means of blocking the d-c grid and plate voltages is required, and the two basic methods (parallel feed and series feed) are shown. The d-c blocking capacitors should have a low

value of reactance, normally a fraction of the tank capacitor reactance. In plate-modulated transmitters the maximum value is limited by the amount of capacitance loading the modulation transformer can stand. A capacitor could be used in series with the tank coil; however, to avoid passing large tank currents through the blocking capacitor, this is seldom done. Coil losses would also be increased because the inductance would have to be increased to overcome the blocking-capacitor reactance. Another type of series feed which overcomes these objections is shown in Fig. 21. D-c, as well as r-f, voltage appears across the tank capacitors, however. Shorter leads from tube to tuning capacitor are possible, giving a better harmonic-current return path and a higher parasitic resonant frequency. Another advantage is that less r-f voltage appears across the series-feed r-f choke, since the impedance at this point is usually much lower than at the plate of the tube.

FIG. 21. Series-fed pi network.

R-f Chokes. The best r-f chokes for use up to 30 Mc, where the plate voltage is only a few hundred volts, seem to be the very common 4-pi chokes rated at 2.5 mh and 100 ma d.c.

Plain solenoid-type r-f chokes are the most satisfactory kind for use across high r-f voltages and over a wide frequency range. They are usually wound with a length of five to ten times their diameter and as small physically as the d-c current and the r-f voltage across the choke will allow. This keeps their distributed capacitance to a minimum. It also keeps the field of the choke as small as possible, so that shields and other objects in the field of the choke do not reduce the series self-resonant frequency and broaden it. R-f chokes must have sufficient inductance for use on the lowest frequency of operation and must have their lowest series self-resonant frequency above the highest frequency of operation.

FIG. 22. Series-fed circuit for increased subharmonic attenuation.

If a suitable compromise cannot be made, it is necessary to use more than one choke to cover the frequency range. They cannot be simply connected in series, however.

Pi-wound commercial chokes often can be used in the amateur bands, but they usually have holes between bands and would burn up at these series self-resonant frequencies.

An interesting choke application in a series-fed circuit useful in doubler stages is shown in Fig. 22. C_1 and L_1 form the plate tank circuit which is tuned to resonance by varying L_1. C_2, for d-c blocking and r-f by-pass, is series-resonant with the equivalent parallel reactance of C_1L_1 at the driving frequency f. $C_2 \cong 1.5C_1$. This places a very low impedance load on the tube at f and results in much higher attenuation of f than would otherwise be obtained. When L_1 is varied for tuning, the two resonant frequencies track across the band.

13. Tank-circuit Design.[1] The basic problem is represented schematically in Fig. 23. In this figure R_L is the required load resistance and Q is the circuit Q. Except for very low values of circuit Q the approximation $X_L = X_C$ is nearly exact. Low Q values are treated later in connection with the L-section design curves. R_L may be

[1] Most of the material in Secs. 13 through 21 is taken from Warren B. Bruene, How to Design R-F Coupling Circuits, *Electronics*, **25**, 134, May, 1952.

determined approximately by the following methods. For class C amplifiers, assume the peak plate-voltage swing to be $0.8E_B$, where E_B is the d-c plate voltage. For high-g_m tubes at maximum plate voltage this figure may be as high as 0.9, and for ordinary triodes with low plate voltages it will be less than 0.8.

Since the power output is known, R_L can be computed from

$$R_L = \frac{e^2 \text{ peak}}{2P} \tag{28}$$

A slightly more accurate value of R_L can be determined from computations of the tube operating conditions using the procedure shown in the previous section.
FIG. 23. Basic circuits for matching high-impedance plate circuit to low-impedance load.

With R_L known, X_c can be found by choosing Q and using Eq. (27), $X_c = R_L/Q$. The actual value of capacitance can now be calculated or read from a reactance chart.

The power loss in a simple tank circuit is given by the ratio of circuit Q to coil Q:

$$\% \text{ loss} = 100 \frac{Q_{ckt}}{Q_{coil}}$$

It should be noted that the resistance in the circuit Q includes the r-f resistance component of the inductor.

In direct capacitance-coupled exciter stages, the load resistance is presented directly to the tube. The load on the tube also includes the losses in the tank circuit, which are very appreciable on frequencies where the circuit Q is high, which may be due to high circuit capacitances.

The tap on the tank coil (Fig. 23*b*) may be used to match the tube to any resistive load R_A which is lower than R_L. When the coil is tapped, there is a mutual inductance between the tapped portion and the untapped portion which must be considered. The equation of impedance match for this circuit is

$$\frac{R_A}{R_L} = \left(\frac{L_2 + k\sqrt{L_1L_2}}{L_1 + L_2}\right)^2 \tag{29}$$

where k is the coefficient of coupling. For a given R_A the load on the tube increases as the tap is moved up the coil.

Capacitance division (Fig. 23*c*) may be used to match a low-impedance grid load to a high-impedance driver tube, since a capacitive return to ground is provided for both plate and grid. For a fixed impedance match the ratio of C_1 to C_2 must remain constant. When the circuit Q is high

$$\frac{R_A}{R_L} = \left(\frac{X_{C2}}{X_{C1} + X_{C2}}\right)^2 \tag{30}$$

and the voltage-transformation ratio is

$$\frac{E_A}{E_L} = \frac{X_{C2}}{X_{C1} + X_{C2}} \tag{31}$$

14. Inductive Coupling. When the load is coupled into the plate tank circuit by means of a link or pickup coil, both resistance and reactance will be reflected in series with the tank coil. Figure 24 shows how the loading changes when the number of turns in the pickup coil is varied. The loading is maximum when the reactance of the pickup coil equals the resistance of the load. Under this condition, the ohms of reactance x_1 reflected into the primary equal the reflected resistance r_1.

Fig. 24. Resistance and reactance reflected into tank circuit as per cent of maximum possible reflected resistance.
The reflected reactance drops rapidly as the pickup coil reactance X_2 is decreased. Therefore, if sufficient loading can be obtained with less pickup-coil inductance, the detuning of the plate tank circuit will be less when the coupling is varied. The re-
Fig. 25. Relation of k to Q for untuned coupling coil.

flected reactance is tuned out when the final plate current is minimized after any other change is made.

The equations for this circuit are as follows:

$$r_1 = \frac{(\omega M)^2}{R_2^2 + X_2^2} R_2 \quad \text{resistance reflected into primary} \tag{32}$$

$$x_1 = \frac{(\omega M)^2}{R_2^2 + X_2^2} X_2 \quad \text{reactance reflected into primary} \tag{33}$$

$$(\omega M)^2 = k^2 X_{L1} X_{L2} \tag{34}$$

The reflected resistance and reactance are independent of the magnitude of the load resistance and pickup-coil reactance and depend only on the ratio X_2/R_2 and the coupling.

FIG. 26. Use of Q meter to determine coupling coefficient.
For example, if the load R_2 is 600 ohms, the inductance required in the pickup coil may actually be greater than the inductance of the plate tank coil, whereas for a 50-ohm load the inductance of the pickup coil will be very small.

Values of k. Figure 25 shows the relationship between k and Q for various values of X_{L2}/R_2 when the coupling coil is untuned. Since maximum practical values of k are around 0.35, this shows that the pickup coil must be near optimum or the plate-tank-circuit Q will become very high.

In most of these tank-circuit designs it is usually necessary to know the coefficient of coupling obtainable from a given physical arrangement. Sample coils can be wound and the coefficient of coupling quickly determined by use of a Q meter and the coefficient-of-coupling chart shown in Fig. 26. The procedure is given on the chart.

In commercial types of plug-in tank coils, the maximum k where the link is in the center of the tank coil is approximately 0.35 to 0.40. When the link is over the end of the coil it is approximately 0.3. When the link is the same diameter as the tank coil and spaced from the end of it slightly, k is approximately 0.2. When long coils

are coupled together k may be very low since little coupling exists in any but the few turns on each end of the adjacent coils.

There is little reduction of k if the link in the center of the tank coil is wound over it on a larger-diameter form. When the link in the center is wound on a smaller diameter, k decreases proportionally to the reduction in diameter.
FIG. 27. Relation of k and Q for tuned coupling circuits.

15. Tuned Secondary Circuits. Figure 27 shows the relation of k to tank-circuit Q for circuits having tuned secondaries. The required value is a function of the product of the two circuit Qs. This chart holds true for all values of Q, even those less than unity, and for both series- and parallel-tuned circuits.

For example, if the plate-tank-circuit Q is 10 and the maximum k obtainable is 0.15, what must be the minimum Q of the antenna tank circuit? To solve this, follow the 0.15 line up to the curve (Fig. 27) and then read Q_1Q_2 of 45 at the left. Since Q_1 was given as 10 then Q_2 must be 4.5 or greater.

It is interesting to note that, when one circuit is parallel-resonant and the other series-resonant and both are capacitance-tuned, they can be tuned across a frequency band and still maintain constant Q_1Q_2 and constant k.

16. Link Coupling. Link coupling is often used to couple two circuits together which are physically separated some distance, as shown in Fig. 28. When the transmission line is very short and can be neglected, the effective coefficient of coupling

between the two tank circuits is

$$k_{eff} = \frac{k_1 k_2}{\sqrt{L_3/L_4} + \sqrt{L_4/L_3}} \tag{35}$$

From this equation it is found that the maximum effective coefficient of coupling is realized when the two links have the same inductance. This means that the link inductances should be equal regardless of the inductance of the tank coils or their circuit Qs. When $L_3 = L_4$, the equation reduces to

$$k_{eff} = \frac{k_1 k_2}{2} \tag{36}$$

Fig. 28. Link-coupled tuned circuits. Maximum effective coupling is realized when the two links have the same inductance.

When the length of the transmission line becomes significant and the current or loss in it becomes important, the two links should be designed for matching to the characteristic impedance of the transmission line. The relationships given in Fig. 25 are again used. The adjustments for obtaining a low standing-wave ratio on the line must be made at the load end. A directional wattmeter or some kind of reflected-power indicator is almost necessary for making the proper adjustment. The coupling k_2 and the tuning of L_2 are adjusted for minimum reflected power, resulting in minimum SWR on the line. The tube is loaded by adjusting k_1 and the plate tank circuit, which includes L_1, and is resonated by the usual plate-current dip.

Fig. 29. Harmonic attenuation and output associated with four basic coupling methods.

17. Harmonic Attenuation. Harmonic-attenuation charts for four different types of tank circuits are shown in Fig. 29.

The actual harmonic current generated in an r-f power amplifier is less than the fundamental, of course. In class C amplifiers with 120 deg of plate-current flow, the second harmonic is 3 db less and the third harmonic is about 9 db less. The second harmonic in a class B linear amplifier is 6 db less than the fundamental. The third harmonic would be zero if the tube were perfectly linear. In practice, linear amplifiers are operated more nearly class AB to achieve better linearity, and the second harmonic will then be a little more than 6 db down from the fundamental. These figures added to the attenuation given in the charts give the harmonic level that will appear in the load.

These charts give the maximum attenuation that can be expected, as stray capaci-

tance coupling and other secondary effects may lower these attenuations appreciably. These charts will not be accurate when Q_1 and Q_2 become less than approximately 10 and 3, respectively.

To calculate the harmonic attenuation of any tank circuit proceed as follows:

1. Find the fundamental current through R_L from $I = \sqrt{P/R_L}$.
2. Determine the fundamental current in the load resistance in the same manner.
3. Determine the reactance of all components at the harmonic frequency.
4. Now assume a harmonic current input equal to the fundamental current through R_L and calculate the current that flows in the load resistance. Take short cuts by neglecting resistance terms in each branch as the difference will be only a decibel or two.
5. Use the ratio of fundamental current in the load from step 2 to the harmonic current calculated in step 4 to calculate the decibel harmonic attenuation of the circuit.

18. The L Network. The L network is a very simple circuit; yet it is the most efficient impedance-transforming circuit available. The L-section design chart shown in Fig. 30 is extremely useful in solving nearly all kinds of direct-coupled tank problems.

Example 1: Find the values of X_C and X_L required to match 40 to 200 ohms resistance.

Solution: Find 40 ohms at the bottom of the chart and follow this line up to the intersection of the 200-ohm line extending over from the left-hand scale. The X_C curve (dashed) through this point is 100 ohms and the X_L curve (solid) is 80 ohms, which is the solution.

Example 2: Find the value of X_C that will give a Q of 10 in a tank circuit when the load on the tube is 3,000 ohms.

Solution: The tube load corresponds to R_2 on the chart as it is across the capacitance. Find 3,000 ohms on the R_2 scale and follow across to the diagonal line labeled $Q = 10$. The X_C curve passing through this point is 300 ohms, which is the solution. It can also be noted that the equivalent resistance in series with the tank coil must be 30 ohms.

The L network can be used to match impedances which contain both resistance and reactance. If a low-impedance reactive load is to be matched to a high resistance, the procedure is as follows:

Example 3: Find the values of X_L and X_C required to match $40 + j50$ to 200 ohms resistance.

Solution: Match 40 ohms to 200 ohms as in the first example. The reactive component is in series with X_L, so X_L must be corrected by this amount; so $80 - 50 = 30$ ohms for X_L; X_C remains at 100 ohms. If the reactive component had been $-j50$ then the corrected X_L would be $80 - (-50) = 130$ ohms.

If a low resistance is to be matched to a high-impedance reactive load, the procedure is to convert the reactive load to its equivalent parallel resistance and reactance.

Using lower-case letters for series components and capital letters for equivalent parallel components, equations for this conversion are

$$R = \frac{r^2 + x^2}{r} \tag{37}$$

$$X = \frac{r^2 + x^2}{x} \tag{38}$$

The network reactances are then found on the chart which match the two resistances. The equivalent parallel reactance is combined with X_c to get the corrected value of X_c.

Example 4: Find the values of X_L and X_C required to match 40 ohms resistance to $100 + j100$.

Solution: The equivalent parallel components of $100 + j100$ are $R = 200$ and $X = 200$ ohms inductive. Now find X_L and X_C for matching 40 to 200 ohms. In this case X_C is found to be 100 ohms and this must be corrected to match or tune out the inductive component of the load. Corrected X_C =

$$\frac{100(200)}{100 + 200} = 67 \text{ ohms}$$
FIG. 30. Design chart for determining optimum component values for L, T, pi, and pi-L networks. Inductive reactances are shown solid; capacitive reactances are dashed.

If the reactive component had been capacitive then it replaces part of X_C and the corrected X_C would be

$$\frac{200(100)}{200 - 100} = 200 \text{ ohms}$$

19. Pi Networks. The pi network can be used to perform the combined functions of a plate tank circuit and an antenna-matching circuit and accomplishes this with a

minimum number of circuit elements. It can match a tube to a wide range of load impedances and still maintain the desired values of plate-tank-circuit Q.[1] They should be used only in unbalanced-grid or plate tank circuits. When used only for impedance matching or harmonic attenuation, they may be used in balanced form.

The conventional pi network has certain impedance-matching limitations and will not always efficiently match a tube to "just any old piece of wire for an antenna." The lowest load resistance that can be matched is approximately[2]

$$R_A = \frac{R_L}{Q^2} = \frac{X_C^2}{R_L} \tag{39}$$

Other limitations depend on the choice of inductance and loading capacitor.

A simple method of determining the values of L and C is to treat the pi network as two separate L sections, each matching into a common imaginary resistance r as shown in Fig. 30. The values of R_L and R_A must be known or found first; then Q is chosen. Now all four capacitive and inductive reactances are found by Fig. 30. Add the inductive reactances together since actually a single inductor is used. Knowing the reactances of these elements, their actual inductance and capacitance can be determined in the usual manner.

Example 5: Find L and C required to match a tube load of 2,000 ohms to a 300-ohm flat transmission line at 7 Mc for a plate-circuit Q of 10.

Solution: Find the intersection of 2,000 ohms and $Q = 10$; then read $X_{C1} = 200$, $X_{L1} = 200$, $r = 20$. Now match this r of 20 ohms to the 300-ohm load. From the intersection of the 20-ohm and 300-ohm lines read $X_{C2} = 80$ and $X_{L2} = 75$. Find total X_L by adding X_{L1} to X_{L2} and get 275 ohms. Therefore $C_1 = 113$ μμf, $L = 6.25$ μh, $C_2 = 285$ μμf.

When the load impedance contains a reactive component, it must be converted to its equivalent parallel resistance and reactance. Then find the values for matching to this equivalent parallel resistance. Correct X_{C2} to tune out the equivalent parallel load reactance and the pi-network values are solved.

20. T Networks. Simple T networks are often used to match one low impedance to another because the values of inductance and capacitance required are of more practical sizes. Also they are often inserted in series with a low-impedance transmission line to provide additional harmonic attenuation. In broadcast-station service they are designed by choosing a suitable value of fixed capacitance and using adjustable taps on the two coils for proper matching. The T-network problems are also easily solved by considering them as two L sections (Fig. 30) and then combining the capacitances.

When using T networks for impedance matching only, keep the Q of the sections as low as practical to avoid unnecessary circuit losses. For harmonic attenuation, use Qs of around 5 or 6 in each L section. Higher Qs do not give much more harmonic attenuation but do increase the losses proportionally.

21. The Pi-L Networks. This circuit is becoming increasingly popular for the final tank circuit when the load is a coaxial transmission line. It makes economical use of the components required and in general provides more harmonic attenuation than other circuits and less circuit loss. The second harmonic output from a class C amplifier stage will be approximately 50 db down from the carrier.

To determine the component values of this circuit, break it down into L sections shown in Fig. 30 and proceed as above.

NEUTRALIZATION

The undesired effects of grid-to-plate capacitance C_{gp} of an r-f amplifier tube can be greatly reduced by using a circuit which balances out or neutralizes these effects.

[1] Bruene, W. B., Pi-network Calculator, *Electronics*, **18**, 140, May, 1945.
[2] Note that R_A is the actual load and R_L is the load needed by the tube for efficient power transfer.

22. Capacitance Effects. The effect of C_{gp} on the effective tube input capacitance is given by

$$\text{Input capacitance} = C_{in} + C_{gp}(1 + A\cos\theta) \tag{40}$$

where C_{in} = tube input capacitance
C_{gp} = grid-to-plate capacitance
A = voltage amplification from grid to plate
θ = phase angle of plate load

In an unneutralized tetrode amplifier with a C_{gp} of 0.25 $\mu\mu$f and a voltage gain of 30, a calculation shows that 7.5 $\mu\mu$f is added to the input capacitance. This may not cause serious detuning at medium r-f frequencies but at high frequencies it may, depending upon the amount of total tuning capacitance and the circuit Q. Triode stages must be neutralized because, with 20 $\mu\mu$f of C_{gp} and a gain of 7, the increase in input capacitance is 160 $\mu\mu$f, which cannot be tolerated. This is particularly true if the tube voltage gain varies with modulation as in a grid-, screen-, or plate-modulated amplifier. The reactance variation with modulation would cause very severe r-f phase shift over the modulation cycle.

The input resistance of the grid is also affected by this grid-to-plate capacitance. It is given by the equation

$$\text{Input resistance} = \frac{1}{C_{gp}(A\sin\theta)} \tag{41}$$

This resistance is in shunt with the grid current loading, grid-tank-circuit losses, and driving-source impedance. When the plate circuit is inductive, there is energy transferred from the plate to the grid circuit through C_{gp} (positive feedback), which introduces negative resistance in the grid circuit. When this shunt negative resistance across the grid circuit is lower than the equivalent positive resistance of the grid loading, circuit losses, and driving-source impedance, the amplifier will oscillate.

When the plate circuit is in resonance ($\theta = 0$), the input resistance due to C_{pg} becomes infinite. As the plate circuit is tuned to the capacitive side of resonance, the input resistance becomes positive, and power is actually transferred from the grid to the plate circuit. This is why the grid current in an unneutralized tetrode r-f amplifier varies from a low value with the plate circuit on the low side of resonance to a high value on the high side of resonance. Grid current, of course, is a common indication of r-f voltage on the grid, but it is the voltage change which is of primary concern. In a pentode or tetrode amplifier operating class A or AB_1, the effect of plate-to-grid feedback can be observed by placing an r-f voltmeter across the grid circuit and observing the change as the plate circuit is tuned through resonance.

If the amplifier is overneutralized, the effects reverse so that with the plate on the low side of resonance the grid voltage is high, and on the high side, it is low. One useful "rule-of-thumb" method of checking the neutralization of a stage (assuming it is nearly correct to start with) is to tune both grid and plate circuits to resonance. Then, observing the r-f grid voltmeter, tune the plate circuit to the high-frequency (low-C) side of resonance. If the indication goes up, more neutralization is required, and if it goes down, less is required. This indication is very sensitive in a neutralized triode class C amplifier, and correct neutralization exists when the grid voltage (or current) peaks at the plate-current dip. In tetrode power amplifiers this indication is less pronounced. Sometimes in a supposedly neutralized tetrode amplifier, there is practically no change in grid voltage as the plate circuit is tuned through resonance, and in some amplifiers it is unchanged on one side of resonance and drops slightly on the other. Another observation sometimes made is a small dip in the center of a broad peak of r-f voltage. These various effects are probably caused by coupling from the plate to grid circuit through other paths which are not balanced out by the neutralizing circuit used.

The grid-reaction method of neutralization is preferred because it can be used with any type of neutralizing circuit. Some neutralizing circuits contain a small amount

of feedback and adjusting for minimum feed-through power does not give the correct neutralizing adjustment. If minimum feed-through power is essential, then this must be considered the selection of the neutralizing circuit.

23. Coil Neutralization of Triodes. Coil neutralization has been used frequently in high-powered amplifiers in the broadcast-frequency and in the lower h-f ranges. A coil L_n is placed across C_{gp} and resonated with it to balance out its effect, as shown in Fig. 31. A d-c blocking capacitor must be connected in series with the neutralizing coil. Sometimes a small variable capacitance placed across the coil is used to make the neutralizing adjustment if a means of trimming the inductance to the correct value is not convenient. This circuit is capable of excellent neutralization, although perfect neutralization would require an infinite-Q neutralizing coil. There is no r-f feedback and no fed-through power. It can be adjusted by removing d-c plate voltage and adjusting for minimum r-f voltage across the plate circuit, as well as by the grid-reaction method. Another feature is that the grid input capacitance is equal to just
Fig. 31. Coil-neutralizing scheme.
Fig. 32. Plate neutralization.

the grid-to-filament capacitance plus strays. The tube output capacitance is essentially all stray capacitance. The tube is neutralized at only the frequency where $X_L = X_{C_{gp}}$. For this reason this circuit is used principally in transmitters that operate on one fixed frequency.

24. Plate Neutralization. Figure 32 shows a neutralizing circuit capable of good neutralization with very little feed-through. A split-stator tuning capacitor is used and C_n is approximately equal to C_{gp}. The voltage at the lower end of the plate tank circuit is approximately equal and opposite in voltage to that on the plate side. Proper adjustment of C_n then balances the effect of C_{gp}. The equation for neutralizing balance is

$$\frac{C_n}{C_{gp}} = \frac{C_{1B}}{C_{1A}} \tag{42}$$

It is essential that the stray capacitances across C_{1A} and C_{1B} be equal to maintain neutralization accurately when the tank capacitor is tuned to another frequency requiring a different capacitance setting. If necessary, a small padding capacitor can be added to balance them.

Theoretically, the voltage at the lower side of the tank circuit is not exactly 180 deg out of phase with the plate voltage unless the tank-circuit Q is infinite. For this reason low values of plate-tank-circuit Q must be avoided when using plate neutralization, or the power output must be taken directly from the tube plate with an additional output network.

This circuit is of the broad-band type in that the neutralizing adjustment remains constant when tuned to any frequency within a broad range of frequencies. It should be understood that the tube is neutralized at just the one frequency to which the amplifier is tuned. Neutralization is lost when the plate circuit, which forms part of the neutralizing circuit in this case, is tuned off resonance. The stage remains stable and does not oscillate because the gain of the amplifier also becomes very low when the plate tank circuit is off resonance. Particular note should be made of the

fact that C_{gp} is not neutralized at parasitic frequencies. In fact, in some low-frequency parasitic cases, the neutralizing capacitance is effectively in parallel with C_{gp}.

Plate neutralizing has the disadvantage that the power loss in the plate tank coil is about twice the losses in a single-ended plate circuit because twice the inductance is required. The large circulating current and energy storage in the neutralizing half of the plate tank circuit have little value other than supplying a neutralizing voltage.

25. Grid Neutralization. A grid-neutralized circuit is shown in Fig. 33. A balanced grid tank circuit is used instead of a balanced plate tank circuit. Negative feedback is inherent in this circuit. In some applications, such as class B linear amplifiers, this may be acceptable or desirable, while it may be very undesirable in
Fig. 33. Grid neutralization.
Fig. 34. Feedback inherent with grid neutralization.

some amplitude-modulated amplifiers. Figure 34 shows this feedback more clearly. For neutralization

$$\frac{C_n}{C_{gp}} = \frac{C_{1B}}{C_{1A}}$$

where C_{1A} and C_{1B} include all tube and stray capacitance across them. The feedback voltage is the plate voltage e_p stepped down by the capacitance-voltage division of C_{gp} and C_{1A}.

Another point of interest in this circuit is that the voltage across C_{1B} is higher than across C_{1A}. This is because the current i_2 in the neutralizing branch adds to the circulating grid tank current i_3 while the plate-to-grid capacitive current subtracts from i_3 in C_{1A}. The voltage drop across each capacitor is equal to its reactance times the current flowing through it.

This grid-neutralizing circuit should have its final adjustment made under normal full-power operating conditions using the grid-reaction method. The grid current (or voltage) should peak when the plate is at resonance and fall off symmetrically when tuning it to each side of resonance.

The effective input capacitance across the grid tank circuit due to the tube interelectrode capacitance and the neutralizing circuit is

$$C_{\text{in}} = \tfrac{1}{2}C_{gf} + \tfrac{1}{2}C_{gp}$$

The equivalent value across each half of the grid tank is twice this value. The output capacitance across the plate tank circuit is

$$C_{\text{out}} = C_{pf} + 2C_{gp}$$

Grid neutralization has the advantage that any type of single-ended output network can be used. This minimizes power loss and uses the fewest components.

26. Push-pull Cross Neutralization. Cross neutralization is nearly always used in push-pull triode amplifier circuits. It is ideal in that all voltages and currents remain in balance and there is no feedback. The two neutralizing capacitors C_{n1}

and C_{n2} (in Fig. 35) should be set to the same value and adjusted together. The adjustment can be made with the plate voltage off by exciting the grids and adjusting for minimum voltage in the plate circuit. This can be sensed with a neon bulb, a flashlight bulb in series with a pickup loop, or any sensitive r-f detector. The grid-reaction method can also be used.
FIG. 35. Push-pull cross-neutralized circuit.

The neutralizing capacitors add some capacitance across the input and output circuit. The equivalent grid-to-grid input capacitance is

$$C_{\text{in}} = C_{pg} + \tfrac{1}{2}C_{gf}$$

From plate to plate the capacitance is

$$C_{\text{out}} = C_{pg} + \tfrac{1}{2}C_{pf}$$

The superior performance of cross neutralizing was undoubtedly one of the principal reasons for its high popularity for many years.

27. Triode Neutralizing-circuit Design Considerations. Usually a good bit of engineering is required to obtain best performance of any of these three wide-band neutralizing circuits for triodes. Low-inductance leads and maintenance of balance in balanced circuits over the frequency range are essential. A point often overlooked is that these neutralizing circuits can contain resonances which may cause parasitic oscillations. Many of these considerations are related to the operating frequency, tube size and construction, size of components, value of C_{gp}, and the circuit chosen. Class C amplifiers usually do not need to be neutralized as accurately as class B linear amplifiers. In general, good neutralization is easy to obtain up to 5 or 10 Mc but care must be used above 10 Mc in medium- and high-powered stages. Conventional neutralized triode stages are seldom used above 20 or 30 Mc. Cathode-driven (grounded-grid) circuits are usually used in this region because the neutralizing requirement is practically eliminated by the screening action of the control grid and the low input impedance.

There are many other neutralizing circuits but they are falling into disuse because, in general, they are not easily adapted to rapid frequency changing.

28. Neutralization of Tetrode Tubes. In addition to high power gain, tetrodes have very low values of C_{gp}. Usually it is low enough to prevent oscillation when the stage is properly tuned and loaded. Shielding is necessary to isolate the grid and plate circuits so that C_{gp} is the largest remaining coupling element. It is generally desirable to neutralize tetrodes, however, to reduce the reaction of plate tuning on the grid drive. This is particularly true in high-gain linear amplifiers operating class AB.
FIG. 36. Bruene neutralizing circuit for tetrodes.

Any of the broad-band neutralizing circuits described for use with triode tubes can also be used with tetrodes. The neutralizing capacitor C_n is very small and a small post mounted near the tube provides sufficient capacitance to the tube plate. The balanced tank circuit used for grid or plate neutralization of triodes is avoided in the circuit shown in Fig. 36.[1] The split-stator tuning capacitor and the extra coil loss are avoided. The out-of-phase voltage is obtained across C, which also serves as the grid-tank by-pass capacitor. It is similar to conventional grid neutralizing except that the out-of-phase voltage across C is much less than the grid voltage across C_{gG}. In

[1] Bruene, Warren B., Single-ended Tetrode Final, *CQ*, August, 1950, p. 11.

the illustration C_{gG} represents all capacitance from grid to ground which includes the tube-input capacitance, all stray lead and component capacitance to ground, and the output capacitance of the driving stage if it is capacitance-coupled. The relationships for neutralization are

$$\frac{C_n}{C_{gp}} = \frac{C}{C_{gG}} \tag{43}$$

Typical values of C lie in the region of 200 to 2,000 $\mu\mu$f and C_n is then usually about ten times C_{gp}.

A small amount of negative r-f feedback is inherent in this circuit; so adjusting for minimum r-f feed-through does not give proper neutralization, although it can be used to get into the region of proper adjustment. The grid-reaction method gives good results, particularly in class C amplifiers. Some tetrode amplifiers have very little plate-current dip at resonance when properly loaded. This is particularly true of class AB_1 tetrode amplifiers. Also, the grid-voltage peak may be difficult to distinguish. A more sensitive indication is the peak in power output or drive to the next stage at the plate-current dip. Adjusting the neutralizing capacitance to make the power-output peak coincide with the plate-current dip usually results in a very accurate neutralizing adjustment. The peak in d-c screen current is usually a more sensitive indication of plate tuning than the plate-current dip. This can be used if a meter is provided in the screen circuit.

FIG. 37. Tube elements involved in plate-to-grid coupling.

The screen by-passing lead impedance has a pronounced effect on the neutralization of many power tetrodes.[1] In fact, they may become self-neutralized at some frequency in the v-h-f region. Above this frequency they are overneutralized and require the addition of plate-to-grid capacitance. This is characteristic of power tetrodes using rods to support the screen. Figure 37 illustrates how the tetrode interelectrode capacitances (shown dashed) are involved with inductance L, which is in the screen by-pass connection. R-f voltage on the plate of the tube causes a current to flow through C_{ps} and L. A voltage appears on the screen that is out of phase with the plate voltage. The grid is coupled to this r-f voltage by C_{gs}. At some frequency this will just neutralize the effect of C_{gp}. The effective value of L can be reduced by partially series-resonating it with a variable capacitor to obtain neutralization. In general, it is better to keep L at a minimum by using a very-low-inductance screen by-pass capacitor and short connecting leads. Above the self-resonant frequency a small amount of capacitance shunted across C_{gp} will produce neutralization. The neutralization adjustment changes with operating frequency since an inductive element is involved.

Many of the more recently developed transmitting-type tubes use a cone to connect the screen to a ring terminal. This greatly reduces the internal screen-lead inductance. Screen by-pass capacitors of very low inductance can be constructed which form a ring around the tube. Silvered-mica rings generally form the dielectric for the smaller transmitting-type tubes. This reduces the series screen inductance to such low values it is insignificant.

By-passing the ring-seal screen terminals of the larger power tetrodes is more difficult, however. Undesirable resonances may appear in the by-pass capacitor because of its large physical dimensions. The wavelength of a standing wave in dielectric material is shorter than the wavelength in air by the square root of the dielectric constant. For example, one wavelength at 200 Mc in air is about 5 ft. In a dielectric with a dielectric constant of 25, the wavelength is only 1 ft. Resonance in the frequency range where parasitic plate and grid resonances occur must be avoided.

One method of circumventing this problem is to connect the ring screen terminal
[1] Eitel McCullough, Inc., "The Care and Feeding of Power Tetrodes," Application Bulletin No. 8, 1951.

directly to the chassis deck all around its periphery. This provides the best possible isolation of the tube input and output circuits, as shown in Fig. 38. The neutralizing holds over a wider frequency range and parasitic tendencies are greatly reduced. The filament is operated at a negative voltage equal to the value of the d-c screen voltage. The grid-blocking and the filament-by-pass capacitors have this additional value of voltage across them; otherwise their requirements remain the same.
Fig. 38. Grounded-screen power amplifier.

MODULATION

29. Types of Modulation. An r-f wave must vary in some manner to carry intelligence. The process of varying the wave in accordance with the signal to be transmitted is called modulation. Some types of r-f signals do not use a carrier, since it actually contains no information. Single side band is the conversion of an audio signal to an r-f frequency either with or without inversion. This is identical to just one side band of an a-m signal. Pulse modulation is limited to microwave frequencies, since it uses much more spectrum space. It is very useful in microwave-relay systems because it has a good signal-to-noise ratio and the pulse can be reshaped at each relay station, which substantially removes all noise.

Fig. 39. Effect of key-click filter on keyed wave shape.

Certain letters with subscripts have been adopted to designate the various types of transmitter modulation or r-f emission. Table 1 is reproduced from the FCC, General Rules and Regulations, Part 2—Frequency Allocations and Treaty Matters.

30. Keying. Conventional on-off keying has generally been referred to as "c.w." although the official designation is A_1. It is used when manual sending and receiving methods of code transcription are employed.

Undesirable keying characteristics are chirps, clicks, and backwave. Key clicks are caused by turning the carrier on and off too fast as the key is closed and opened. A continuous pair of side-band frequencies extends out from the carrier up to 100 kc in extreme cases. A key-click filter introduces a time constant to slow down the rate of carrier rise and fall as shown in Fig. 39, which greatly reduces the clicks and limits them to a narrow region near the carrier frequency. The method of shaping the keyed wave depends upon the keying circuit used. Frequency multipliers and class C amplifiers tend to square up the wave shape, since they operate in the region of saturation. This effect varies with changes in gain which may be due to operating on various frequencies. This reduces the effectiveness of wave shaping in an early keyed stage and also lengthens the mark period as shown in Fig. 40.

Fig. 40. Effect of class C amplifier on keyed wave shape.

Keying and wave shaping are sometimes done in the final power-amplifier stage to

Table 1. Modulation Symbols

Type of modulation of emission	Type of transmission	Supplementary characteristics	Symbol

avoid this effect. Chirps are caused by a small but rapid change in frequency as the carrier is keyed on or off. This is particularly troublesome when the oscillator itself is keyed. Also the keying of a later stage may change the oscillator supply voltages or the load impedance on the oscillator, resulting in a chirp. Wave shaping lengthens the time of frequency change and makes the chirp more noticeable. With no wave shaping the frequency change is so rapid it sounds like a click. Isolating the keyed stage with a buffer stage and using well-regulated oscillator supply voltages can reduce chirp to a negligible value.

Backwave is the small amount of carrier leaking through the keyed stage. This

is minimized by use of a frequency multiplier following the keyed stage and class C amplifier stages biased to beyond cutoff in the key-up condition. Keying the oscillator, of course, will eliminate backwave completely. When very low backwave is necessary, chirp due to oscillator keying can be avoided by employing a keyed stage *with wave shaping and an associated circuit which turns on the oscillator instantly* when the key closes. The chirp is over then before the keyed-stage output rises appreciably. A time delay keeps the oscillator keyed on until the keyed-stage output has decayed nearly to zero. This system is called *time-sequence keying.*

FIG. 41. Types of keying circuits.

A mixer exciter will have no backwave on the carrier frequency if the mixer stage is keyed so the carrier frequency does not exist in the key-up condition.

Two typical keying circuits are shown in Fig. 41. They may be keyed directly by a hand key, by a relay, or by a radiotelegraph machine.

31. Frequency-shift Keying (FSK). This form of modulation has been widely adopted for radioteleprinter use because it produces a definite signal on both mark and space. It gives improved circuit reliability and the ability to operate with lower signal-to-noise ratios. The standard amount of frequency shift is 850 cps. The mark frequency is 425 cps above the assigned carrier frequency and the space frequency is 425 cps below it. Other values of shift, such as 600 cps to as low as 40 cps, have been used. Wave shaping is employed to limit the band width required for passing the third or fifth harmonic of the shortest mark-space cycle.

A FSK unit is commonly used to provide a keyed input signal to the exciter of a conventional c-w transmitter. These units contain a 200-kc master oscillator which

FIG. 42. Block diagram of a frequency-shift-keyer unit.

is frequency-shift-keyed by means of a reactance tube across the tuned circuit. This keyed output is mixed with the output of a crystal oscillator or other stable frequency source in the range of 1.8 to 4.3 Mc. The keyed unit output in the 2.0- to 4.5-Mc range is fed to the transmitter exciter where it is multiplied by 2, 4, or 8 to generate the carrier frequency. The amount of frequency shift in the 200-kc oscillator must be reduced by the amount of multiplication following the keyer unit to maintain 850-cps shift at all carrier frequencies. Figure 42 shows a block diagram of a typical circuit.

32. High-level Plate Modulation. This method of amplitude modulation has been very popular because it permits high over-all transmitter efficiency and there are no critical tuning adjustments. A typical class B modulator with a modulated

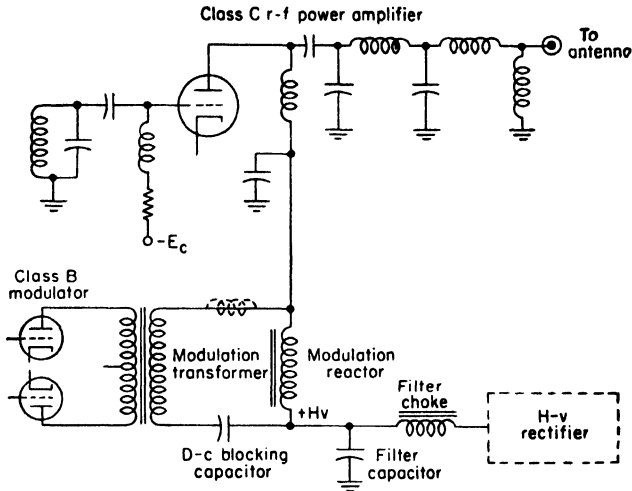
class C r-f power-amplifier circuit is shown in Fig. 43. The class B audio stage is called the modulator, although the modulation actually takes place in the class C power-amplifier stage. The operating conditions of the class C amplifier are chosen


FIG. 43. Circuits for plate modulation.

so that its r-f output voltage is directly dependent upon the voltage supplied to it by the d-c power supply and the modulator (see Fig. 44). Enough r-f grid drive is required so that the r-f plate voltage is always in a saturated condition. This means that more grid drive would not have a noticeable effect on the r-f plate voltage. The fixed bias E_c is usually sufficient to cut off plate current if excitation fails. A grid resistor is used to develop enough bias so that the tube operates in the general region of twice cutoff. This allows the grid-bias voltage to vary over the modulation cycle and results in more linear modulation. Some large transmitters employ a small amount of grid-modulating voltage for the purpose of allowing the use of less driving power and for obtaining lower modulation distortion.

FIG. 44. Voltage relationships in plate modulation.

The peak audio-power-output capability of the class B modulator is equal to the unmodulated d-c plate-power input of the class C stage at 100 per cent modulation. For example, the over-all efficiency of a 10-kw transmitter PA stage may be 75 per cent, which includes plate efficiency and r-f output network losses. This requires a d-c plate input of 10/0.75, or 13.33, kw.

The peak modulator-power output must then also be 13.33 kw. The average power is half of this, or 6.67 kw, for a sine-wave modulating voltage.

The average power depends upon the audio wave shape and varies from perhaps 1 kw for speech or music audio input to 13.3 kw with square-wave audio input in this example. The average modulation level is quite low (20 to 30 per cent) in some classes of service, such as broadcasting. A saving can be made in the size of the modulation transformer in these cases. It must still be capable of the full peak power on a short-time basis (a few minutes), but the low average power results in less heating, and hence allows a size reduction.

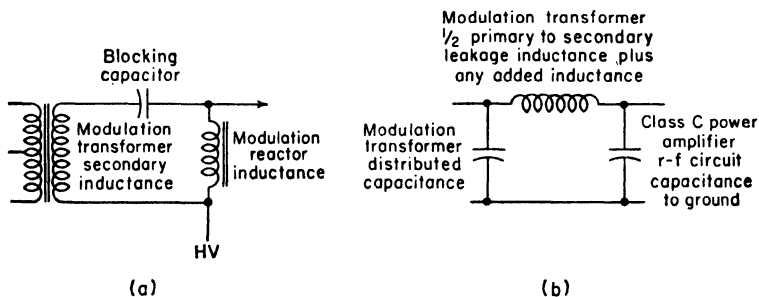
The sizes of the modulation transformer, reactor, and blocking capacitor are determined largely by the low a-f response desired. The size of these components can be kept to a minimum by choosing their values to form a high-pass filter[1] at low audio frequencies as shown in Fig. 45*a*. This causes higher audio current in the high-voltage filter capacitor which necessitates an increase in its size.


FIG. 45. High-pass and low-pass filters in modulator circuit.

Finding the optimum design with respect to size, cost, and frequency response generally requires numerous trial computations. The high-frequency response is determined by the primary-to-secondary leakage inductance of the modulation transformer along with its distributed capacitance and the effective capacitance of the r-f stage. These elements can be designed to form a low-pass filter as shown in Fig. 45*b*. Usually it is desirable to keep the modulation-transformer leakage inductance at a minimum and add the necessary inductance with a separate small inductor. It is necessary to have very low leakage inductance between halves of the primary winding to minimize distortion due to the modulator switching transients.[2] These techniques are generally used in large transmitters which have an a-f range of 50 to 7,500 cps or greater.

High-fidelity transmitters below the 1-kw power level usually use a modulation transformer designed to carry the d-c plate current of the class C stage in its secondary. This increases the size of the modulation transformer, but this is more economical since the modulation reactor and the blocking capacitor are eliminated. In voice-communication transmitters, this is usually done up to the 5-kw power level. The frequency response of these transmitters is about 150 to 3,500 cps.

33. Plate Modulation of Tetrode Class C Amplifiers. The screen of a tetrode r-f power amplifier must be modulated along with its plate. This is necessary to avoid flattening of the positive modulation peaks. The amount of d-c screen-voltage modulation is not critical and varies from about 50 to 75 per cent depending upon the tube type. A screen winding on the modulation transformer can be used, as shown in Fig. 46. It is essential that the screen-voltage modulation be in phase with the plate-voltage modulation. Differences in leakage inductance and distributed capaci-

[1] Lee, Reuben, "Electronic Transformer and Circuits," 2d ed., p. 192, Wiley, 1955.

[2] Sah, A. Pen-Tung, Quasi Transients in Class B Audio-frequency Push-pull Amplifiers, *Proc. IRE*, **24**, 1522, November, 1936.

tance along with different relative reactive loads on the two modulation-transformer windings can cause the voltages to get out of phase, particularly at high audio frequencies. The screen by-pass capacitor value in the class C stage is a compromise
Fig. 46. Modulation of screen and plate.
Fig. 47. Self-modulation of class C tetrode screen.

between good r-f by-passing and the shunting effect of this capacitance on the screen-modulation circuit.

The screen of most tetrodes will modulate itself if a suitable impedance is placed in series with the d-c screen supply. A resistor may be used but this requires a much higher screen-supply voltage. A reactor with 5 or 10 henrys inductance can be used
Fig. 48. Class B modulator load line.

with most of the higher-powered tetrode tubes.[1] Figure 47 shows a circuit which uses such a reactor in series with a resistor since some resistance is desirable in the screen circuit of class C tetrode amplifiers to reduce the possibility of excessive screen dissipation with variations in grid drive.

34. Class B Modulator Design. *The data sheets for most tubes suitable for modulator service list maximum tube ratings and show a typical operating condition.* It is quite easy to compute an optimum operating condition for other d-c plate voltages or power outputs, however. The modulator tube chosen must deliver a peak power output equal to the class C amplifier d-c plate-input power. This peak power is equal to the modulator-tube peak plate-voltage swing multiplied by its peak plate current as shown in Fig. 48.

The end point of the load line should be established at a point at least 5 per cent below the maximum limit to allow for variations in tubes, imperfect power-supply regulation, etc. From the end point of the load line, the modulator-tube operating conditions can be computed using the following equations.

$$\frac{2i_p}{\pi} = \text{d-c plate current per pair of tubes} \qquad (44)$$

$$\frac{\pi e_p}{4E_B} = \text{plate efficiency at maximum signal with sine wave} \qquad (45)$$

$$i_p e_p = \text{peak audio power output} \qquad (46)$$

$$\frac{i_p e_p}{2} = \text{rms sine-wave power output} \qquad (47)$$

$$4\frac{e_p}{i_p} = \text{plate-to-plate load impedance} \qquad (48)$$

$$i_p\left(\frac{E_B}{\pi} - \frac{e_p}{4}\right) = \text{plate dissipation per tube} \qquad (49)$$

With a sine-wave audio signal the modulator plate dissipation is greatest when the signal level is such that the peak plate swing is $(\pi/4)^2$ or 61.7 per cent of the modulator d-c plate voltage.

FIG. 49. Class B modulator with low-mu driver.

The choice of modulator zero-signal plate current is a compromise between distortion and zero-signal plate dissipation. A value that produces a zero-signal plate dissipation of one-half the maximum rated tube-plate dissipation is frequently used.

The d-c plate voltage is the same as that used for the class C r-f stage unless a separate modulator power supply is employed. For economy and to avoid the possibility of operating the modulator without a load, a common high-voltage power supply is generally used.

Triode, tetrode, and pentode tubes are all suitable for class B modulators. The choice of modulator tubes is often dictated by the desire to use the same tube type in the modulator as is in the r-f power amplifier. Most low-powered transmitters use beam-power tetrode tubes. In the medium-power range up to 5 kw both triodes and tetrodes are used. Triodes are found in most high-powered transmitters.

The drive for modulator tubes which are driven into grid current must have very good output-voltage regulation. The use of low-mu triodes which have low plate resistance and are coupled to the modulator grids with an impedance-stepdown driver transformer is one method (see Fig. 49). Another method uses driver tubes connected in a cathode-follower circuit, as shown in Fig. 50.

The driver transformer must have a frequency response much greater than the a-f range to be covered. This is necessary because the modulator-grid current is

rich in harmonics and these must be tightly coupled to the driver tube to realize a low driving-source impedance. The transformer phase-shift characteristics are also very important in broadcast transmitters which use audio feedback for distortion reduction.

Some modulator tubes have a grid-current characteristic with a negative slope in it, as shown in Fig. 51. A resonant circuit from grid to ground is all that is necessary for oscillation to take place when the grid voltage is in the region between A and B. The leakage inductance of the driver transformer and the input capacitance of the tube, stray capacitance, and transformer capacitance form a parallel-resonant circuit often in the range of 25 to 50 kc. This parasitic oscillation will show up in the modulator output wave (Fig. 52). Since this negative slope is due to grid emission, it varies considerably from tube to tube. Loading the grid circuit will help in marginal cases, but in others the loading required to prevent oscillation is prohibitive, and the only solution is to eliminate the driver transformer or use another tube type.

FIG. 50. Class B modulator with cathode-follower driver.

The grid-bias supply for class B modulators must have excellent d-c and dynamic regulation. The screen supply for tetrode modulators also must be well regulated.

A solution to these problems is to use modulators operating class AB_1. The plate efficiency is nearly as good with properly chosen tubes, and the grid-bias and driver-regulation requirements are eliminated. Also the driver transformer can be eliminated and either direct or capacitive coupling from driver plate to modulator grid can be used. This eliminates some phase shift which is advantageous when feedback is used. Beam-power tetrodes can be employed as class AB_1 modulators in the low-to medium-powered transmitters, and low-mu triodes (*e.g.*, mu = 4 to 5) are used in medium- and high-powered transmitters. Figure 53 shows a circuit used in a 10-kw transmitter.

FIG. 51. Modulator grid-current characteristic.
FIG. 52. Parasitic oscillations due to negative grid-current slope.

Audio feedback is usually employed in broadcast transmitters to lower distortion and improve the frequency response. Feedback voltage is taken from the modulator plates and is fed back over three stages.

The frequency-response and phase-gain characteristic of the feedback loop must be controlled for about four octaves beyond each end of the desired a-f range to permit the feedback to be effective at all audio frequencies within the required range.

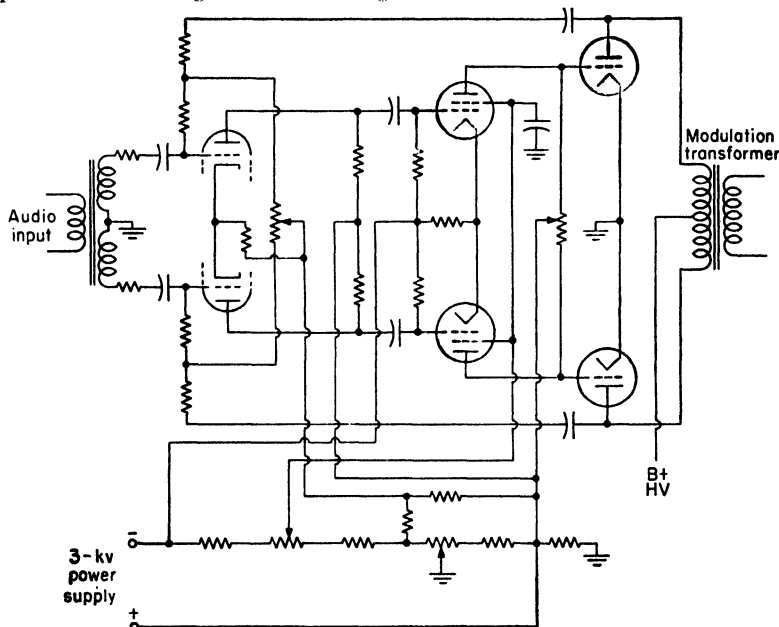
35. Grid, Screen, and Suppressor Modulation. *Prior to the widespread use of high-level modulators, modulation was accomplished by grid-modulating the power* amplifier or modulating an earlier r-f stage.


FIG. 53. Class AB_1 modulator.

Grid, screen, and suppressor modulation are all types of efficiency modulation. The audio voltage on the modulated grid varies the efficiency of the r-f stage, resulting in an a-m output signal. Figure 54 shows how the r-f output voltage varies with grid bias. The fixed bias which determines the carrier level should produce an r-f output voltage of about one-half maximum value. The efficiency of a grid-modulated r-f stage varies from zero at the trough of a 100 per cent modulated envelope to a maximum of about 70 per cent at the envelope peak. The efficiency at carrier level is one-half the maximum value, or about 35 per cent. Similar curves are obtained for screen-voltage variation and for suppressor-voltage variation. For no distortion, this curve would be a straight line up to the maximum level.

FIG. 54. Variation of r-f output voltage with grid bias.

The grid current which is modulated varies greatly with signal level and presents a varying load to the modulator tube. A heavily swamped modulator tube or a circuit with low internal impedance will reduce excessive distortion from this cause.

Because of their low efficiency and relatively high distortion, grid-modulated final r-f amplifier stages are seldom used. Exceptions are transmitters with a grid-modulated driver stage followed by a high-efficiency linear amplifier and small transmitters where efficiency or a-m power level is of secondary importance.

36. High-efficiency Linear Amplifiers. Several types of high-efficiency linear amplifiers have been developed for obtaining a relatively high efficiency at carrier level without the use of the large class B modulator necessary for high-level modulation. In general, they use two tubes. One operates near maximum efficiency at carrier level and is modulated downward on the negative modulation peaks. The second tube functions only on the positive modulation peaks.

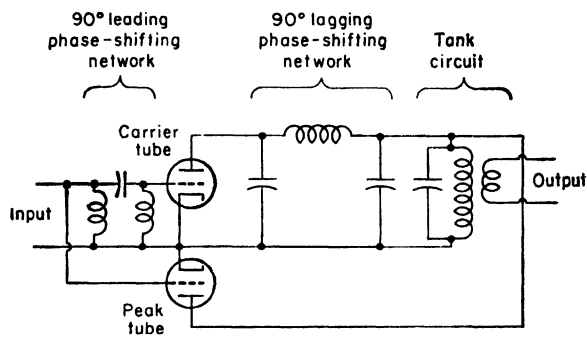
One type still being manufactured uses the Doherty circuit[1] (see Fig. 55). Ninety-degree networks couple the grid and plate of the carrier tube to the grid and plate of the peak tube, respectively. The peak tube is biased so that it operates only on the positive modulation peaks and is cut off on the negative peaks. The 90-deg networks cause most of the r-f load to transfer from one tube to the other over the modulation cycle.


FIG. 55. Doherty amplifier.
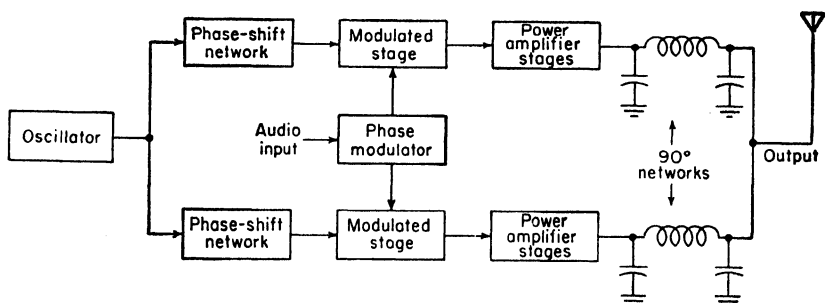

FIG. 56. Block diagram of an outphasing modulation system.

37. Outphasing Modulation. This is another type of high-efficiency a-m modulation in current use.[2] A block diagram is shown in Fig. 56. The crystal oscillator feeds two exciters which are phase-modulated with equal amounts of phase deviation but in opposite directions. Each phase-modulated signal is amplified by a separate string of identical class C amplifiers. The outputs of the two class C power amplifiers are combined using 90-deg networks. The transmitter output is the vector addition

[1] Doherty, W. H., A New High Efficiency Linear Amplifier for Modulated Waves, *Proc. IRE*, **24**, 1163, September, 1936. Witty, W. M., Modern Fifty-kilowatt Broadcast Transmitter, *Electronics*, **28**, 168, March, 1955.

[2] Chireix, H., High Power Outphasing Modulation, *Proc. IRE*, **23**, 1370, November, 1935. Starner, C. J., J. W. Lawson, and C. D. Mulford, The RCA "Ampliphase" Fifty, *Broadcast News*, **84**, 54, August, 1955.

of the outputs of the two amplifiers as shown in Fig. 57. This causes the load on each power amplifier to vary from zero (neglecting r-f network losses) to a maximum at the modulation crest. The r-f plate swing on the tubes remains at a full class C value at all times, resulting in high plate efficiency.

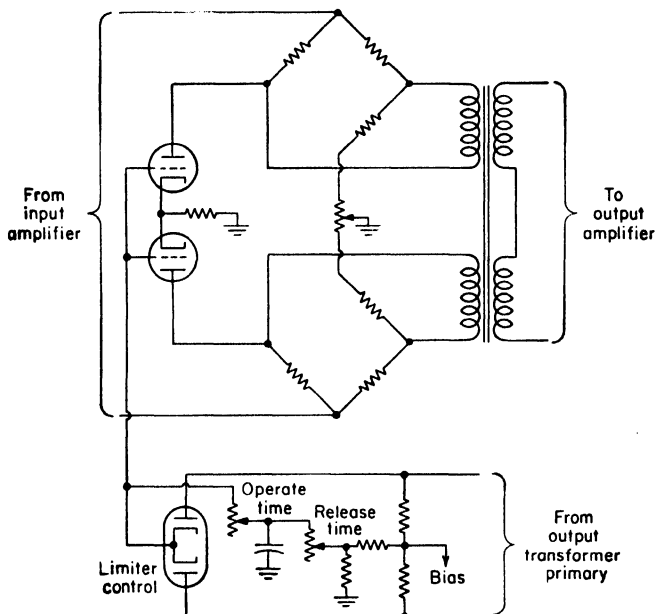
The Doherty amplifiers and the outphasing system both require numerous critical tuning adjustments. This is satisfactory for single-frequency operation but is the
Fig. 57. Vector relationships for producing amplitude modulation.
Fig. 58. Limiting-amplifier gain characteristic.


Fig. 59. Limiter control circuit.

reason these circuits are not used in equipment where the operating frequency must be changed often.

38. Audio-limiting Amplifier. The audio signal should be maintained at a value that will frequently cause 100 per cent modulation on audio peaks. This will help make full use of the transmitter-power capability. Audio-limiting amplifiers are used for this purpose. They contain a gain-reducing circuit that is operated by audio peaks that exceed a given level. Figure 58 shows a typical gain-vs.-signal-level curve.

Many circuits will accomplish this purpose. One is shown in Fig. 59. Limiting amplifiers are often built into the audio section of communications transmitters. Separate units are also used, particularly in broadcast stations. These amplifiers employ a short time constant on gain reducing and a slow time constant on gain return. These are often called the *attack* and *release* time constants. Release time constants vary from as short as 0.1 sec for speech in communications transmitters to 2 sec in some broadcast-station applications.

39. Speech Clipping. This is another method of increasing the average power in the audio signal. Instead of reducing gain, the audio peaks which exceed a given level are chopped off (Fig. 60). The vowel sounds contain much of the speech power while the consonants contain much of the intelligence. Since the vowel peaks are about four times the amplitude of the consonant sounds, it has been found that clipping off half the peaks (6 db of clipping) has only a perceptible effect on speech quality, but it raises the transmitter's average a-m side-band power by approximately 6 db.
Fig. 60. Effects of speech clipping.

Up to 20 db of clipping has been used, and although the naturalness of the voice is degraded, the intelligibility remains high. A low-pass filter following the clipper removes high-frequency harmonics which are above the desired audio range.

Some of the rough sound due to the distortion generated by speech clipping can be eliminated by reducing the audio response of the lower audio frequencies where the strong vowel sounds occur. Less clipping is then required to keep the consonant sounds at full signal level. An audio limiter ahead of the speech clipper will maintain a high average level to the clipper for an additional improvement in modulation effectiveness.

The low-frequency response of the amplifiers and modulators following a speech clipper must be excellent to avoid appreciable tilting of the flat top of the clipped wave.

This type of speech clipping is not desirable in phase-modulated transmitters. An automatic peak-deviation control is more effective.[1]

Clipping audio peaks is not effective in limiting SSB envelope peaks because the audio input wave and the corresponding SSB envelope shape are different. Automatic load control (ALC), which employs a gain-reducing r-f amplifier in the exciter actuated by power-amplifier signal peaks, is more effective.

40. Frequency and Phase Modulation. Generating circuits for these types of communications transmitters are very similar. In fact, the nature of f-m and p-m signals is so similar that one can be converted to the other by applying a 6-db-per-octave slope to the a-f response. A phase modulator will produce f.m. when the audio response falls off with increasing frequency at the rate of 6 db per octave across the audio range. Most p-m circuits have a practical limit as to how many degrees the phase of the carrier can be modulated. If more deviation is required, the modulation is done at a subharmonic of the carrier. Frequency multipliers raise the modulated output to the desired carrier frequency. The degrees of phase deviation are increased

[1] Winkler, Marion R., Instantaneous Deviation Control, *Electronics*, **22**, 97, September, 1949.

by the same multiplication factor. The p-m or f-m signal is generated in the exciter, and class C r-f amplifiers raise the power to the rated transmitter carrier output.

The use of a phase modulator for generating f.m. has the advantage that a stable crystal oscillator can be used for generating the carrier. An f-m master oscillator has relatively poor frequency stability so that its use requires additional circuits for keeping the average frequency precisely on carrier frequency.
FIG. 61. SSB signal in r-f spectrum.

Frequency modulation has a signal-to-noise advantage over a.m. and SSB when the signal is strong enough to cause limiting in the receiver and when large deviation is used. This, of course, consumes more spectrum space and hence is limited to the v-h-f range and above. It is widely used in v-h-f vehicular communication because the transmitter is simpler and less expensive and consumes less power than a corresponding a-m transmitter. It is also widely used in multichannel systems in the u-h-f and microwave regions.
FIG. 62. Filter type of SSB generator.

41. Single-side-band Generator. The function of an SSB generator is to convert the audio signal to an r-f signal either with or without inversion. An SSB signal is one side band of an a-m signal. Figure 61 shows the frequency spectrum occupied by an SSB signal. The other side band and the carrier are substantially eliminated. The term used to express the amount that the undesired side band is reduced is *side-band suppression*. Carrier suppression may be expressed as decibels below the peak envelope power of the desired side band.

FIG. 63. Balanced-modulator circuits.

A block diagram of the filter method of SSB generation, shown in Fig. 62, is used in nearly all commercial SSB transmitters. The audio signal is mixed with an oscillator at an intermediate frequency in a balanced modulator. The output of the balanced modulator contains both side bands but the carrier is substantially eliminated depending upon the degree of balance realized in the modulator. The filter selects the desired side band and rejects the other. The output of the filter is an SSB signal at an intermediate frequency, which
is then raised to the carrier frequency by frequency conversion.[1] Several types of balanced-modulator circuits are suitable for SSB generators. A pair of semiconductor diodes can be used, as shown in Fig. 63*a*, but a diode quad, sometimes called a *varistor*, as shown in Fig. 63*b*, will have fewer undesired output products. Vacuum-tube diodes can also be used in these circuits; however, the balance tends to be affected by the cathode-to-filament capacitance and by filament voltage. A twin triode can also be used, as shown in Fig. 64. A special beam deflection tube, shown in Fig. 65, performs well as a balanced modulator and has the advantage of operating at a higher impedance level.
FIG. 64. Tube type of balanced modulator.
FIG. 65. Beam deflection tube used as balanced modulator.

The diode modulators generally work best at circuit impedances of about 1,000 ohms.

The filter should have a flat response across the desired speech band and very steep skirts to obtain a high degree of undesired-side-band suppression. An i-f frequency of 20 kc is used in some transmitters because satisfactory filters can then be built using high-*Q* coils and capacitors. A frequency this low requires an additional conversion step over exciters which generate the SSB at a higher i-f frequency. Very excellent crystal filters have been developed for use in the 100-kc region and have been in use for many years in transoceanic radiotelephone equipment.[2] Mechanical filters[3] in the range of 250 to 455 kc are being used extensively in voice-communication transmitters.[4] Figure 66 shows a typical response curve of a pair of mechanical filters which will select either side band at a carrier frequency of 300 kc.
FIG. 66. Typical response of mechanical filter for SSB selection.

The i-f frequency of the SSB generator must also be suitable for a frequency-conversion scheme that will have a minimum of undesired mixing products that may appear in the transmitter output.

Two or more SSB signals can be multiplexed together and passed through a common exciter and linear power amplifier. One method, better known as *independent side band*, uses the upper side band of one audio channel and the lower of the other. Figure 67 shows a block diagram of a typical basic circuit, and Fig. 68 shows the spectrum occupied by each channel.
FIG. 67. Independent-side-band generator.
FIG. 68. R-f spectrum of independent side band.

Another method which occupies the same spectrum space but uses the upper side band for both channels is shown in Figs. 69 and 70.

In this example, a separate carrier frequency is used for each channel with 4-kc spacing. Additional channels may be added in the same manner.

Radiotelegraph channels may also be added. For example, FSK oscillators operating at the proper i-f frequencies can provide several radiotelegraph channels in addition to voice channels.

The phasing method of SSB generation[1] has been widely used in amateur radio equipment. Figure 71 shows a typical circuit. A double-balanced modulator is fed two audio and two r-f signals, each of which must be 90 deg apart in phase. When connected as shown, the phase relationship of the side bands generated in the double-balanced modulator is such that the carrier and one side band are balanced out and only the other side band appears in the output. Reversing the two audio inputs will select the other side band. The amplitude and phase of the input signals must be adjusted and maintained to a high degree of accuracy for good side-band suppression. It is very difficult to achieve 40 db of side-band suppression, which is necessary for multiplexing applications. For this reason it has been limited to a great extent to amateur service where lower values of side-band suppression are usable.

FIG. 69. SSB generation using separate carrier frequencies for each channel.

POWER SUPPLIES

42. Power Sources.[2] Fixed transmitters up to 1-kw power rating usually use a single-phase a-c power source. Exceptions are mobile equipment which may operate

[1] Villard, Oswald G., Jr., A High-level Single-sideband Transmitter, *Proc. IRE*, **36**, 1419, November, 1948.

[2] See also Chap. 17.

on 6 to 28 volts d.c. They may use dynamotors or vibrator power supplies to obtain the high voltages required. In the larger aircraft, 400 cps a.c. is generally used. Mobile equipment using these various types of power supplies is found in police cars and taxis, in jeeps, on ships, and in aircraft.

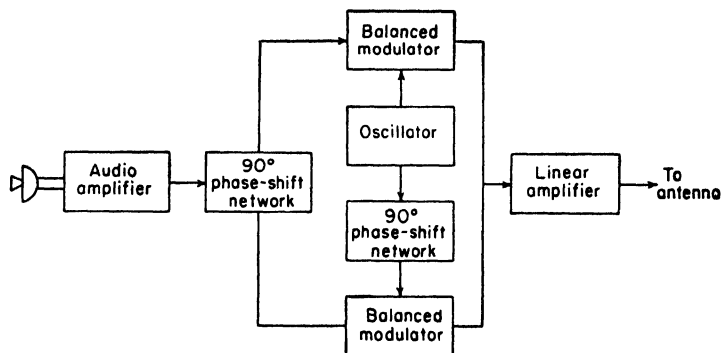
Above 1 kw, a three-phase a-c source is generally used. In the United States a three-phase 230-volt 60-cycle a.c. is generally available. In some countries, a three-phase 380-volt 50-cycle source is very common.


Fig. 71. Phasing type of SSB generator.
Fig. 72. Three-phase full-wave rectifier.

Three-phase full-wave rectifiers have the best plate-transformer utilization, good regulation, and a low ripple output. The ripple frequency is six times the primary a-c frequency, and it is 25 db down from the d-c plate voltage at the input to the filter. For this reason, the filter requirements are relatively small. Figure 72 shows the basic circuit of a three-phase full-wave rectifier used in a high-voltage power supply.

Other types of rectifier circuits are sometimes used to achieve certain advantages. The three-phase half-wave circuit, shown in Fig. 73, requires only three tubes. The ripple frequency is only three times the power-line frequency; so much more filtering is required. A given rectifier tube can deliver only one-half as much d-c voltage in this circuit compared with that of a full-wave rectifier. Figure 74 shows a three-

phase double-Y circuit often used to obtain up to twice the d-c output current obtainable from a three-phase full-wave bridge with a given type of rectifier tube.

It is desirable to connect the rectifier-tube filament transformers so the filament voltage on each tube is 90 deg out of phase with its plate voltage. This minimizes the
FIG. 73. Three-phase half-wave rectifier.
FIG. 74. Three-phase double-Y rectifier.

difference in voltage from each end of the filament to the plate. More uniform emission over the entire filament results, which increases tube life. Some of the larger rectifier tubes have increased ratings in quadrature operation. In some cases a 60-deg phase difference is more practical and nearly the full advantage is realized.

Requirements. In addition to supplying the required d-c voltage and output current, the principal power-supply requirements are adequate d-c regulation, good

dynamic regulation, and low ripple or noise output. Most high-voltage transmitter d-c power requirements are for either an "on-and-off" or a varying-load characteristic. In general, very good d-c regulation is required. High-voltage filters are nearly always used between the rectifier and the load. Generally, this is essential to reduce the output ripple and noise to very low values and avoids modulation of the signals in the amplifiers which receive power from these supplies. The filter chokes inherently place a relatively high impedance between the rectifier and the load so that it is necessary to have fairly large values of capacitance in the output side of the filter. The filter capacitor must be large enough to supply the rapid variations in load current which are impeded by the filter choke. This is particularly necessary when supplying power for class B modulators and class B linear r-f amplifier stages.

43. Rectifier Operation. Small low-voltage power supplies which have a relatively constant load can use vacuum rectifiers. Where better regulation is required, it is necessary to use gas-type rectifiers. They have a low voltage drop which remains fairly constant in the 10- to 15-volt region for all values of current up to their maximum rated values. In general, they have high current capabilities and the low voltage drops result in excellent rectifier efficiency. Mercury-vapor rectifier tubes are the most common gas-type rectifier used. In general, they have very long life when operated within their rated operating conditions. The operating temperature is generally limited to that which will permit the coolest part of the tube to be in the temperature range of 20 to 60°C. The condensed mercury-vapor temperature range is usually listed on the tube data sheets.

When frequent mercury-rectifier-tube failures are encountered, it is often found that they are being operated below their rated temperature. Operating them either too hot or too cool changes the mercury-vapor pressure in the tube from the design value and reduces the peak inverse-voltage capability. This makes them more susceptible to an arc-back. The mercury will condense on the coolest spot in the tube, which should be near the base and within the proper temperature range. There will be some temperature rise in the tube during operation because of filament heat and plate dissipation, which will raise the temperature about 10 to 15°C above the ambient air after about 30 min of operation. Very little temperature rise of the tube envelope occurs during the 30- to 60-sec filament-warmup time, however. This means that the free-air ambient temperature should not be less than the minimum temperature requirement for starting, and it should be 10 to 15°C less than the maximum rated condensed-mercury temperature. A small blast of air near the base of the tube will reduce this 10 to 15°C if operation near the maximum tube temperature is necessary.

The most critical period of rectifier-tube operation is in starting, because a transient voltage peak may occur when the plate transformer is switched on. It is very important in high-voltage circuits for the condensed-mercury-vapor temperature to be correct at this time. Some equipment is provided with heaters to raise the tube temperature when operation at low ambient air temperatures is required.

Equipment which may be subject to wide ambient-temperature variations, such as military or remotely operated stations, uses inert-gas tubes such as the 3B28 and 4B32 in place of the 866A and 872A mercury-vapor equivalents. This type of tube can be operated in ambient temperatures of -75 to $+90$°C. It is pointed out, however, that the life of these tubes is generally shorter and a rough estimate is that they have about one-third the life of their mercury-vapor equivalents. Apparently the gas tends to "clean up," which lowers the gas pressure and reduces the peak inverse-voltage capability.

Vacuum rectifier tubes are used in very-high-voltage circuits because of their higher peak inverse-voltage capability. Also, they are not temperature-sensitive. They have a large voltage drop, however, which results in lower efficiency and poorer regulation, but in the usual high-voltage low-current applications this is acceptable. Typical applications are in high-powered pulsed r-f amplifiers and high-powered klystron amplifiers.

Metallic rectifiers, such as selenium, copper oxide, and magnesium sulfide types,

have been frequently used in power supplies delivering less than 100 volts for energizing relays, etc. They have had limited application in high-voltage transmitter supplies, although one 50-kw broadcast transmitter uses selenium rectifiers and another uses germanium rectifiers exclusively.

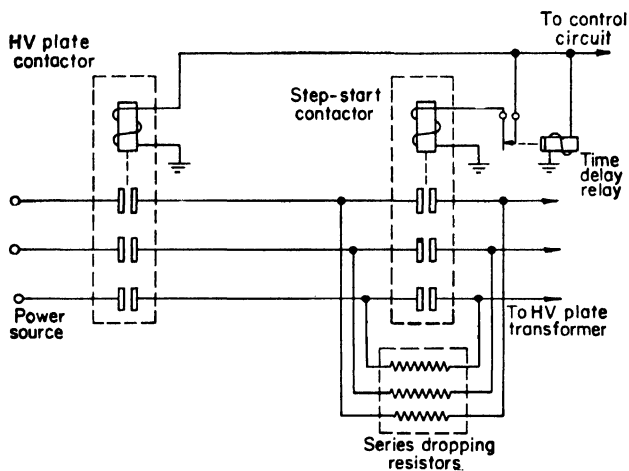
Germanium and silicon junction diode rectifiers have a very low voltage drop, which results in excellent regulation and efficiency. Developments in the field of semiconductor junction rectifiers are very rapid, and it is expected that they will find very wide application. The top ambient-temperature range for germanium rectifiers is in the range of +55 to +85°C, while the silicon types can operate at temperatures up to +150°C and even higher. They are filling many applications where the advantages of small size, low weight, and excellent efficiency are important. Rectifier


FIG. 75. Step-start circuit.

stacks using elements in parallel or in series to obtain higher current or voltage usually have matched rectifier elements. Germanium and silicon rectifiers have very small size and thermal capacity for their ratings, and hence protection against large transients is often necessary.

44. Power-supply Transients. Transient voltages and currents which far exceed the steady-state values are frequently encountered in high-voltage power supplies. These transients tend to be greater when transformers with high-grade steel operate near their maximum flux density. The primary inrush current transient is determined largely by the residual flux in the core, the primary coil inductance in air, and the point on the primary voltage wave at the instant of closure. For this reason, the transient may vary greatly from one switch closure to the next. Peaks up to ten to twenty times the maximum rated line current may be encountered.

Plate-transformer secondary-voltage-transient peaks may be twice the normal secondary voltage and can be observed on an oscilloscope. An examination of repeated starts on both single-phase full-wave circuits and three-phase full-wave circuits showed occasional peaks of twice the normal a-c voltage. The principal significance of these peaks is that they can cause rectifier tubes to arc back if this peak exceeds their inverse-voltage capability. For this reason, it is desirable to operate rectifier tubes in circuits where the normal peak inverse voltage does not exceed one-half the rated peak inverse voltage. When this is not possible, *step-start* circuits are sometimes used. One type starts the transformer with resistors in series with the primary leads, as shown in Fig. 75. After a short time delay (usually less than 1 sec), these resistors are shorted, which brings the rectifier up to full voltage operation.

Greatly reduced primary current transients and a smaller secondary voltage transient result.

A third kind of power-supply starting transient is caused by the charging current required to bring the voltage up on the filter capacitors. This current is determined largely by the capacitance involved, the inductance of the chokes, and the value of the steady-state d-c supply voltage. This transient can cause excessive current in the rectifier, and to limit it some large high-voltage power supplies start with a resistor in series with the filter capacitor (Fig. 76). The capacitor charges through this resistor, which is shorted out after a time delay.
FIG. 76. Filter-capacitor charging-current-surge limiter.

CONTROL CIRCUITS

Small transmitters, such as those used in mobile service, may have very simple control circuits. The "on" switch applies power to the heaters of all cathode-type tubes. A push-to-talk button on the microphone controls a relay, which in turn applies plate voltage and puts the transmitter on the air. This keeps the power drain at a minimum and reduces wear on the high-voltage generator, which is usually a vibrator or dynamotor. Some transmitters use quick-heating filament-type tubes in the power stages, which also are operated by the push-to-talk relay for further reduction of stand-by power drain. Larger mobile transmitters will have some of the control-circuit functions described in the next paragraphs.

The number of control-circuit functions depends to a large extent upon the size and complexity of the transmitter. Push buttons are usually used to initiate certain control functions. Relays then complete the function in the proper manner. These circuits provide necessary protection to tubes and components against improper sequencing and malfunction. Also, interlock provisions are made to minimize the possibility of personnel coming in contact with dangerous high voltages. These three functions of circuit control, equipment protection, and personnel protection are interrelated and are all integrated into the transmitter control system. The function and purpose of various parts of control circuits in common use are as follows.

45. Filament On-Off Switch. The filament-control push button or switch initiates a sequence of functions that applies power to all filaments, and starts the cooling system and time-delay circuits that make the transmitter ready for the application of plate power. When operated to the "off" position it shuts the transmitter down.

46. Filament Heater Control. The filament "on" switch operates a relay which energizes the filaments of all heater-type tubes and the filaments of the high-voltage rectifier tubes.

47. Blower Control. One or more blowers are used to cool the tubes and to provide general transmitter cooling and are usually started by the filament "on" circuit. The life and reliability of many components are greatly dependent upon temperature; so proper cooling is essential. Many high-power tubes require the application of cooling before filament heating power is applied. Air interlocks prevent application of power to tubes which require cooling when the blower is not operating for any reason. Some air interlocks have a small vane in the blower-outlet air stream to close a switch when the air velocity is adequate. Another type uses a switch actuated by the air pressure developed in a plenum chamber by the blower. A "blower off" delay circuit is often provided in large transmitters to cool tubes and components after

all power is removed from them when shutting down. The blower keeps running until a time delay of a few minutes has expired. Then the blower is automatically stopped.

48. Power-amplifier Filament. Separate relays may control power to the filament of large transmitting-type tubes. When filament cooling is required for the tube, the filament relays are interlocked with the blower air switches.

49. Time Delay. Mercury-vapor rectifier tubes require a warmup time of 30 sec to 1 min before the application of plate voltage. Cathode-heater-type tubes may require a heating time of 30 sec. A time-delay circuit which is energized when filament power is applied assures the proper time delay to avoid tube damage. At the end of the delay period, a contact in series with the high-voltage primary-control circuits is closed, which allows application of plate voltages. Motor-operated time-delay units use a gear-reduction train to operate a switch after a certain number of motor revolutions. Pneumatic, dashpot, and mercury time-delay relays depend upon the slow flow of air, oil, or mercury through a small orifice. Thermal time-delay units use a heater to cause bending of a bimetallic strip. Each has its particular characteristics and field of usefulness. Some reset almost instantly, and others, like the thermal type, reset very slowly. An ideal type for tube protection would remain operative for a second or two after power removal and then only reset at the same rate that the tube filaments cool. This achieves the shortest delay in getting the transmitters on the air following a power interruption.

50. Bias-supply Control. It is essential that bias voltage be applied to the various power-amplifier stages before plate or screen voltage. In some transmitters the bias-supply plate transformer is energized as soon as the time delay has operated. If semiconductor bias-supply rectifiers are used, bias may come on with the application of filament power. In other transmitters, the bias supply is not energized until the plate "on" switch is energized. An interlock is nearly always provided. It may be an extra contact on the bias plate relay, but a relay operated by the bias-supply output voltage will protect against bias-supply failure also.

51. Low-voltage Plate-supply Control. The plate voltage on the smaller tubes in the exciter and audio-amplifier stages is sometimes applied automatically as soon as the vacuum-type rectifier tubes warm up. If mercury-vapor rectifier tubes are used, the plate circuit cannot be energized until the time-delay period has expired. These supplies are generally large enough to warrant switching with the high-voltage supplies. Provisions are usually made so that these low- and intermediate-voltage power supplies can be operated without energizing the high-voltage supply. This is a useful feature for tuning and trouble shooting.

52. High-voltage Plate-supply Control. The transmitter control circuits are sequenced and interlocked so that everything else must be on and functioning before the high-voltage plate transformer can be energized. A single exception is the application of screen voltage to some power tetrodes. Screen dissipation in many of them will be excessive if screen voltage is applied without plate voltage. An interlock relay actuated by d-c plate voltage prevents this. Relays in small- and medium-powered transmitters, and remotely operated circuit breakers in high-powered transmitters, energize the plate transformer.

53. High-voltage Step-start Circuit. Very high current and voltage transients often occur when power is instantly applied to a high-voltage plate transformer. Primary-line-current surges may be up to ten or twenty times normal line current, and secondary voltages up to twice normal are common. An excellent step-start circuit places resistors in series with the transformer primary when the primary power circuit is closed. The resistors limit the transients to relatively small values. After a short time delay (less than 1 sec), the resistors are shorted, and full voltage is applied to the plate transformer primary.

54. Sequence Start. In many transmitters, particularly those suitable for remote control, each part of the transmitter is energized in the proper sequence automatically.

Initiation of the transmitter start function may be by a single push button or a remotely operated relay. This function may be combined with the "plate on" push button, which closes a holding relay. This energizes the filament control circuit and all circuits are energized in order, and finally the high-voltage plate power comes on.

55. Overload Relays. Medium- and high-power tubes are nearly always protected from excessive plate current by overload relays in plate or cathode circuits. These relays remove the high-voltage primary power if the plate or cathode current exceeds a predetermined value. The relay coils are shunted with a low-value resistor to avoid the effects of the reactance of the relay coil to a-f current components. The more elaborate overload relays have a flag which indicates that it has operated. The value of tripping current can be adjusted on some relays directly, and on others the shunt resistor is adjustable. Overload relays are quite effective in class C amplifiers where the plate current rises considerably when the plate circuit is out of tune.

56. Overload Recycling. Many overloads that occur when the transmitter is in normal operation will clear themselves as soon as the high-voltage d.c. is removed. A switching transient or lightning surge may cause an arc-over, for example. For this reason, most large transmitters in installations where off time must be kept at a minimum use a recycling circuit to cause the transmitter to come back on once or twice before staying off. Some transmitters will try once at full power and, if the overload persists, will go off and try again on a low-power position before shutting down. Automatic-reset provisions are usually made so that, if only one overload occurs which clears itself, the counting circuit returns to normal after several seconds of delay.

57. Primary A-c Circuit Protection. Fuses and circuit breakers are used to protect the primary circuits and some of the larger components, such as transformers and motors. The major a-c branch circuits are protected, but small transformers may be protected as a group because they have such high internal impedance that an overload would not cause enough increase in primary current to blow a fuse. Switch-type circuit breakers are common in large transmitters, because they can be used as a switch as well as for circuit protection.

58. Personnel Protection. High voltage is very dangerous to human life; therefore, precautions are made to prevent accidental contact with it. Various safety standards have been set by the different transmitter manufacturers. Protection is nearly always provided against access to voltages above 250 volts. Some rather elaborate protection schemes have been devised. Nearly any scheme can be cheated, and sometimes this is necessary when servicing the equipment. The operator or service technician interested in staying alive does not take chances.

Door interlock switches will remove all high voltage in an enclosure when the door is open or an access panel is removed. These switches are connected either in series with the plate-transformer primary circuit or in series with the transformer-control relay coil.

High-voltage shorting switches ground high-voltage circuits when a door is opened. This is an added protection used in circuits with over 1,000 volts on them because the primary door interlock can fail. Also, it assures that the high-voltage filter capacitors are discharged. A cautious operator will always use a grounding stick in addition before touching anything in a high-voltage circuit.

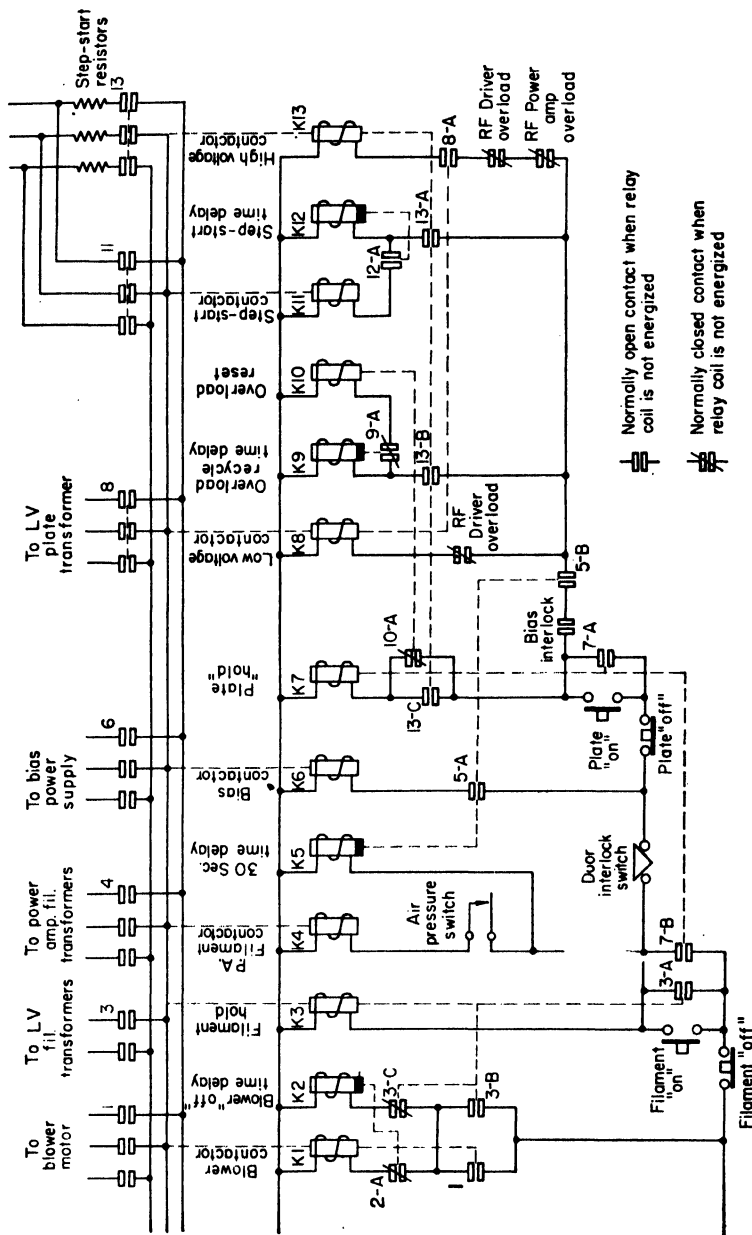
59. Typical Transmitter Control Circuit. A control circuit typical of those used in 5- to 20-kw transmitters is shown in Fig. 77. The requirements of each transmitter are different, and more or fewer functions may be necessary. In general, the control-circuit complexity is proportional to the power rating of the transmitter. This control circuit is separated from the primary power circuits and is fused or protected by a separate circuit breaker. Small transmitters frequently have their control circuits mixed in with the primary circuits. This may save some relays and is acceptable in low-power circuits, since the primary fuses or other protections have low enough ratings to protect the control-circuit components also.


FIG. 77. Transmitter power-control circuit.

The function of each relay in Fig. 77 is shown, and dashed lines aid in associating the contacts with the proper relay coil. Before starting the transmitter, all primary power disconnect switches and circuit breakers must be closed. Pressing the filament-on button ("fil on") closes the circuit through the filament-hold relay K3. One of its contacts, K3-A, parallels the "fil on" contacts and interlocks the relay so it remains energized when the push button is released. (Note: All four of the filament and plate "on and off" push buttons are of the momentary-contact type.) This relay also may energize the filaments of all low-power tubes and the high-voltage rectifier tubes. Another contact, K3-B, causes the blower contactor, K1, to be energized, which in turn starts the blower. This blower supplies cooling air to the power-amplifier tubes as well as general transmitter cooling. When sufficient air pressure is developed, the "air pressure switch" closes and energizes the "PA fil" contactor. This interlock function assures the presence of cooling air when the power-amplifier filaments are on. The "30 sec time delay" relay K5 was also energized when the "fil on" button was pressed. Its contacts remain open for 30 sec to allow the rectifier filaments in the bias, low-voltage, and high-voltage power supplies to reach operating temperature before plate voltage can be applied to them. At the end of the 30-sec time-delay period, K5-A closes and energizes the "bias plate" contactor, K6, providing the "door interlock switch" is closed. Actually, there may be several door interlock switches in series, and all must be closed before any bias or high-voltage plate power can be applied. The primary function of door interlock switches is personnel protection, but the cooling-air system may not function properly if either a door or an access panel is open. A bias interlock relay whose coil is in the bias supply d-c output circuit becomes energized as soon as the bias supply is operating and closes the "bias interlock" contact. This prevents application of plate voltage without bias being present, as a protection to the amplifier tubes. The sequence of functions initiated by pressing the "fil on" button is now completed, and the transmitter will remain at this stage of operation until another sequence is initiated.

Pressing the "plate on" push button initiates the steps which bring the transmitter into full operation. The "plate on" switch energizes the "plate hold" relay K7 through the contacts K10-A which are closed. It holds itself closed by means of its contact K7-A when the push button is released. The "low voltage" contactor, K8, also operates, providing the 30-sec time delay has elapsed and the "bias interlock" contact is closed. The "driver overload" relay contact will be closed. Its purpose is to open the low-voltage plate-voltage-supply primary circuit if driver plate current becomes excessive. When the "low voltage" relay operates, its contact K8-A energizes the "high voltage plate" contactor K13, which applies primary power to the high-voltage plate transformer through the "step-start resistors." Closure of K13-A energizes the "step-start time delay" relay which delays closing of the "step-start" contactor by a fraction of a second. The transmitter is now in full operating condition.

The auxiliary contact K13-B on the "H.V. plate" contactor energizes the "overload recycle time delay" relay, and through its normally closed contact, K-9A, the "overload reset" relay, K10, will be energized. This opens K10-A. As long as K10-A is open, an overload in either the r-f driver or power amplifier will cause all low-voltage and high-voltage plate power to be removed. The "plate on" button must be pressed again to apply plate power.

After a period of 5 sec, the "overload recycle time delay" relay will open K9-A. This deenergizes K10, and K10-A closes. Now when an overload causes plate power to be removed, it will be reapplied immediately. If the overload has cleared itself, the plate power will remain on. If not, the second opening of an overload relay contact within 5 sec will cause plate power to remain off because K7 will be deenergized. This is called a "two-shot" overload circuit because it takes two successive overloads within a 5-sec period to shut off plate power.

Plate power may be removed by pressing the "plate off" push button. Filament power may be removed by pressing the "fil off" push button. The blower will continue to run because its contactor is kept energized by the "blower off time delay," K2. When its time delay has elapsed, K2-A opens and releases the "blower contactor," K1. The transmitter is then completely shut down.

This control circuit has a sequence-start provision. Pressing the "plate on" button operates the "plate hold" relay, which has a contact, K7-B, across the "fil on" push button. The "plate hold" relay holds itself on by means of K7-A. The entire transmitter will come on with each step in the proper sequence and can be shut down by pressing the "fil off" button, which turns off all plate power. The blower continues to run until the blower time delay has expired as before.

CARRIER-FREQUENCY CHANGING

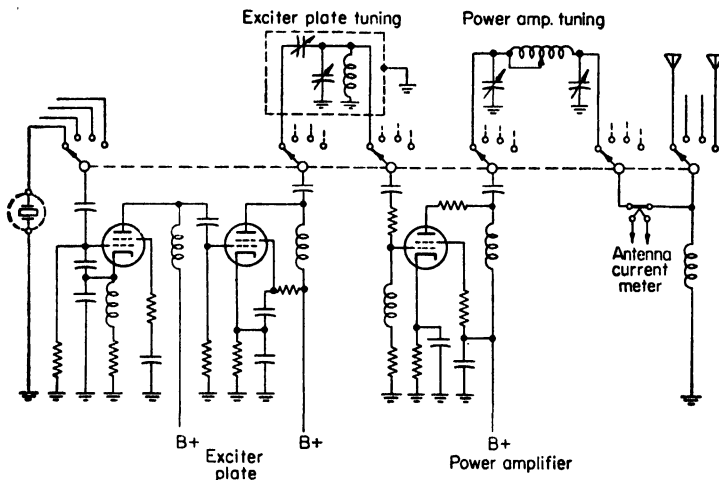
60. Frequency-changing Needs. Some communications services require nearly instantaneous shift in carrier frequency. One example would be to answer a calling aircraft on the frequency it may be monitoring. In some applications a few seconds' delay is acceptable, and in others a minute's delay will cause little inconvenience. In still other circuits, there is little advantage in having quick frequency-shift provisions at all, and a frequency change time of even 5 or 10 min is acceptable. Some h-f communication stations and short-wave broadcast stations change frequency on a fixed schedule. Also, there are those which change to a new frequency when the propagation conditions require it for communicating to some fixed point; and it is frequently necessary to use different frequencies when communicating to stations located at various distances from the transmitter.


FIG. 78. Simplified schematic of band-switched transmitter.

61. Channel-switching Transmitters. An instantaneous frequency change is usually accomplished by some means of switching. Some of the h-f transmitters in the 50- to 100-watt class, which are set on the operating table, switch tuned circuits by a ganged wafer switch operated by a control knob on the front panel. A selection of frequencies is provided, and plug-in components allow any frequency to be set up on each channel. Figure 78 shows a simplified schematic of such a transmitter. Any channel may be selected simply by rotating the band switch when all circuits are properly tuned.

This same principle is used in 200- to 1,000-watt transmitters, except that relays or some type of remotely operated switches are used. Two- and four-channel transmitters are most common.

62. Multiple R-f Bay Transmitters. A very popular method of quickly changing frequency in the 2- to 3-kw power size is accomplished by switching complete r-f units. Several units are connected to a common power supply. A common modulator is used for amplitude modulation. The power supply generally has enough capacity to operate two or three r-f units simultaneously. As many as 12 separate r-f units are used in some installations with a common power supply. The crystal ovens and filaments of the heater-type tubes are operated continuously. When a channel is selected for transmission, the keying and modulator circuits are switched to the r-f unit which is tuned to the selected frequency. The thoriated-tungsten filaments, the blower, and the low-voltage circuits are energized by additional relay switching. The

channel-change time depends upon the switching circuitry, but usually it takes less than a second or two. Figure 79 shows a simplified diagram of such a switching method.

This type of communication transmitter is commonly located several miles from the operator's position and is remotely controlled over telephone lines. Telephone-type switching is used to turn the transmitter on and off, and to select the channel and type of emission. A second control function is keying or push-to-talk carrier control.
FIG. 79. Block diagram of a switched multibay transmitter.
FIG. 80. Simplified four-wire remote-control system.

A third remote connection is required to carry audio for voice modulation. Sometimes a remote indication of the on-off condition of the transmitter and the channel selected is furnished. Two telephone pairs can perform all these functions. Figure 80 shows the basic circuits used to accomplish this. When the remote distance is several miles or more, these functions all usually are carried on one nonmetallic telephone pair, *i.e.*, one having a repeater or transformer in it so that d.c. cannot be transmitted. One tone (60 cps) is used for dial pulsing and a second (3,500 cps) for keying. Filters at the transmitter separate these tones and rectify them to create the

d-c voltages required by the control circuits. Figure 81 shows a block diagram of such a system.

63. Autotune[1] Transmitters. A second basic method of changing frequencies is one which mechanically tunes each control to a preset position set up for each channel. One method uses an Autotune system in which the tuning conditions for up to 10 channels can be preset. Figure 82 illustrates the basic principle. When changing to a new frequency, the tuning control rotates counterclockwise to its stop or home position. The cam drum then rotates to the position which will allow the pawl corresponding to the selected channel to drop. The tuning-control shaft on which the stop drum
FIG. 81. Simplified two-wire remote-control system.
FIG. 82. Autotune principle.

is mounted rotates clockwise until the pawl drops into the notch which stops rotation. The clutch which couples this mechanism to the driving motor then slips until the motor is stopped automatically. Figure 83 shows the basic circuit of a locally controlled Autotune system.

Telephone-dial control can also be employed for remote operation of the Autotune. The frequency-change time generally is on the order of 3 to 30 sec, depending on the type of Autotune used. Figure 84 shows a simplified schematic of a dial-control circuit for remotely operating an Autotune system.

64. Servomechanism Tuning. In another method used in several medium- and high-powered transmitters for frequency changing a servomechanism controlled by a potentiometer is provided for each tuned element. A bank of preset potentiometers

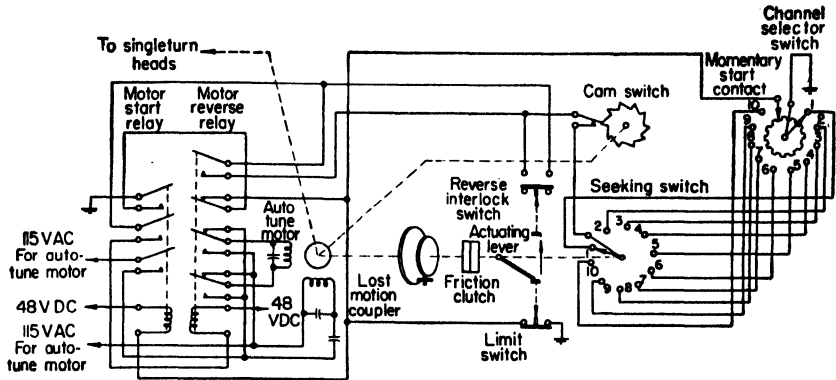
[1] Registered trade-mark of Collins Radio Co.


FIG. 83. Electrical details of the Autotune system.
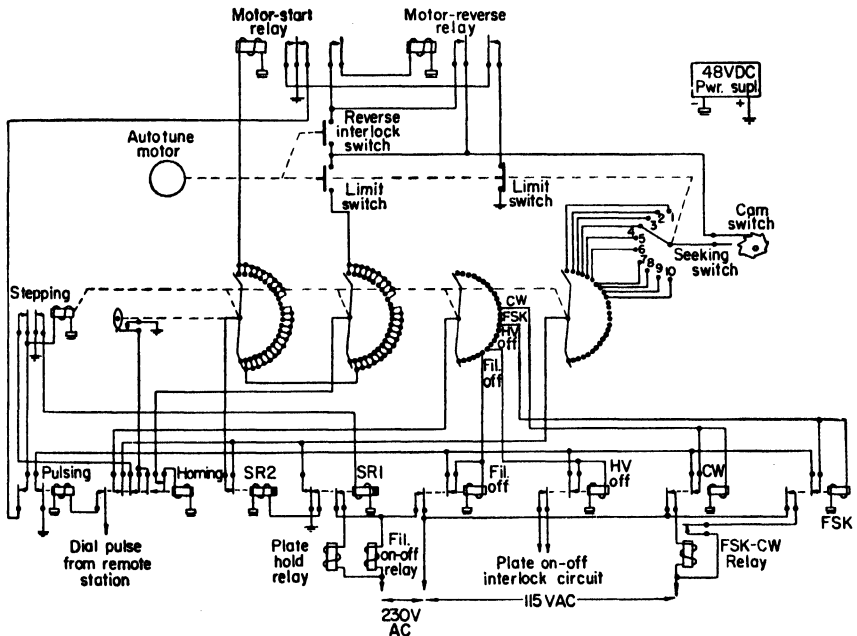

FIG. 84. Control of remote Autotune system.

may be provided, and the group which has been adjusted for a particular carrier frequency can be selected by a switch. Figure 85 shows a simplified schematic of a servomechanism with the switching provided for several control potentiometers. This circuit is duplicated for each servomechanism, and the switching for all potentiometers is ganged together.

65. Autopositioners.[1] Mechanical positioning of circuits which are tracked to provide a linear tuning curve can be accomplished by means of Autopositioners. These mechanisms are able to position a shaft accurately to any of an integral number of

[1] Registered trade-mark of Collins Radio Co.

shaft positions per revolution. For example, an accurate stop position may be obtained for 8, 10, 12, or 20 equally spaced stops per revolution. This type of positioning has been used in the v-h-f and u-h-f transmitting equipment which allows any selection from hundreds of channelized operating frequencies.

66. Automatic Tuning and Loading. Servo-tuned transmitters can be made completely automatic by obtaining a control signal directly from the tuned circuits.
FIG. 85. Simplified schematic of a servomechanism.

R-f phase detectors compare the phase of the r-f plate voltage on a tube with the grid voltage. A d-c signal is obtained when the plate voltage is not 180 deg out of phase with grid voltage and the d-c polarity indicates to which side of resonance the plate circuit is tuned. This information can be used to operate the servo and cause it to tune the circuit to resonance. A typical phase-detector circuit is shown in Fig. 86. The range of pull-in is less than an octave; so wide-range transmitters use some means of coarse tuning to approximate frequency. One method uses a wide-band frequency detector (see Fig. 87). Its output is positive or negative d.c. which may be combined with the phase-detector output to obtain both coarse tuning and accurate fine tuning by just sensing the r-f signal.[1] Combined detector voltages are shown in Fig. 88. This type of circuit is capable of a tuning accuracy of ±5 deg, which is usually closer to exact resonance than an average operator will tune a stage by observing plate-current dip. The phase detector provides a very sensitive indication of resonance.
FIG. 86. Phase-detector circuit.

Automatic loading of a power amplifier may be accomplished by adjusting loading for the correct value of plate current in a class C amplifier. Usually a fixed ratio of d-c plate current to d-c plate voltage is used.

Class B linear amplifiers may be loaded for the correct ratio of r-f plate swing to r-f grid swing.

The elements of the output network must be designed and ganged so they can be

[1] DeLong, V., Automatic Tuning for High-power Transmitter, *Electronics*, **29**, 134, July, 1956.

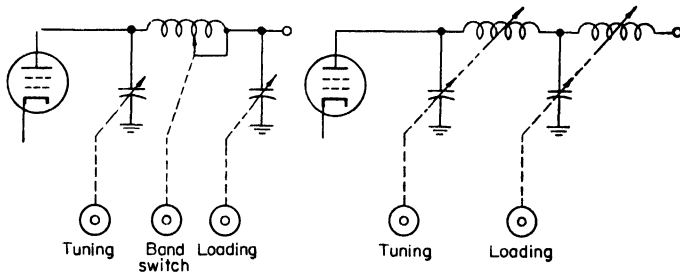
adjusted completely by one tuning and one loading control unless other information is also provided. The coil may be band-switched from information received from the frequency-setting control on the exciter, for example. Figure 89 shows two ways an output network may be ganged. It is essential that rotation of any tuning control in a given direction will always produce the same effect. For example, a clockwise rotation of the loading control should always increase loading. If it ever changes effect under any conditions of load or mistuning, the servo system will lose directional sense.
FIG. 87. Broad-band frequency-detector circuit.
FIG. 88. Combined output of phase and broad-band frequency detector.


FIG. 89. Ganged output networks for automatic tuning and loading.
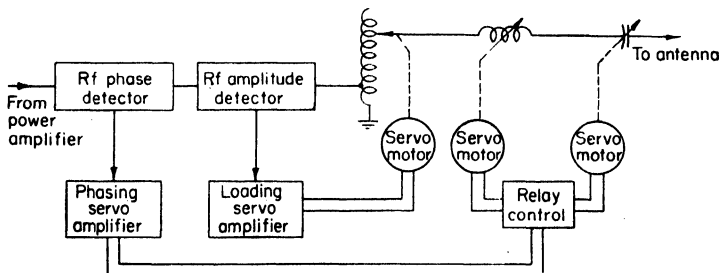

FIG. 90. Automatically tuned antenna coupler.

67. Automatically Tuned Antenna Coupling. A simplified schematic of an automatically tuned antenna coupler is shown in Fig. 90. These have become widely used in aircraft installations. The antenna coupler is located where the antenna enters the fuselage. It matches the antenna to a coaxial cable which connects the coupler unit to the transmitter. Two servomechanisms are required. The r-f detectors are located at the 50-ohm coupler input. One detector compares the phase

of the line current with the line voltage. Its output is positive or negative d.c. depending upon whether the r-f current phase leads or lags the phase of the r-f voltage. This causes the one servo to run in the proper direction to produce a pure resistive input impedance. The second detector compares the relative amplitude of the input current and input voltage. It causes its servo to run until the ratio of voltage to current equals the characteristic impedance of the transmission line.

When this type of antenna coupler is used, the transmitter output network can be designed to match the power amplifier to the characteristic impedance of the transmission line with only one tuning servo. Careful ganging and tracking of the network elements are essential to maintain constant loading over a wide frequency range. This system is most commonly used in air-borne installations and in some mobile ground stations.

ANTENNA-FEED METHODS

The antennas used at transmitting and receiving stations contribute greatly to the effective communicating power of a system. A piece of wire long enough to load the transmitter and working against a poor ground can easily require several times as much transmitter power as a simple dipole of the correct height. A directional antenna that concentrates the radiated power in the desired direction and at the optimum vertical angle of radiation will give further improvements of 3 to 20 db, providing a stronger signal at the receiver or permitting use of less transmitter power.

Practically all good antennas use a transmission line to carry the r-f power from the transmitter to the antenna. This may be a few feet of small coaxial cable in the case of a v-h-f radio installation in a taxicab to ½ mile of 600-ohm open-wire line feeding a rhombic antenna. Some power is always lost in a transmission line, a loss which must be balanced against the optimum antenna location and a convenient transmitter location.

68. Transmission Lines. Since the use of transmission line is becoming almost universal, the transmitters are being designed to feed lines that are most common to each class of service. For example, m-f broadcast stations use vertical antennas working against a ground system; so they are most conveniently fed with an unbalanced line. Unbalanced-line impedances of 50 and 75 ohms are quite standard, but unbalanced lines using four, six, or more wires and having an impedance of about 250 ohms are used also in some installations to reduce transmission-line cost. Broadcast transmitters therefore are designed for feeding these impedances.

In the h-f range, the 600-ohm open-wire line is most common for medium and high power. It is an efficient low-cost type of line that is easy to construct. Since it is a balanced line, it adapts itself well to feeding balanced antennas which are most common in the h-f range.

Since the radiation losses and discontinuities of open-wire lines become excessive in the v-h-f and u-h-f regions, coaxial line is generally used in this range. Wave guides are used from the u-h-f region on up in frequency.

69. PA Output Network Considerations. The trend in transmitter power-amplifier design has been away from push-pull and toward wider use of single-ended circuits. Inductive coupling also is being used less in h-f transmitters which must operate over a wide range of frequencies because of the problem of adjusting the inductances and the coupling between them. Output networks which use simple pi and T sections provide the greatest amount of harmonic attenuation with the smallest number of elements and the smallest number of tuning controls.

Some means of matching the power amplifier to the transmission line must be provided. This can be done in the transmitter output network. A 600-ohm matching network is shown in Fig. 91.

When L_{2A} and L_{2B} are separate coils with no mutual coupling, the balance section is one type of Alford network.[1] Typical values of reactance for L_{2A} and L_{2B} would be 400 ohms, but they can vary over a wide range. L_{2A} and L_{2B} must be equal.

[1] Alford, A., Matching Networks, U.S. Patent 2165086.

The reactance of C_3 is one-half the coil reactance. When mutual coupling exists between the coils, the reactance of C_3 decreases and would become zero if unity coupling existed. This circuit has also been referred to as an autotransformer with its leakage inductance tuned out by C_3. The input impedance of this balanced network contains an inductive component so that C_2 must have more capacitance than would be required for matching a resistance load of 150 ohms, which is the equivalent parallel resistive component at this point with a balanced 600-ohm resistive output load.

FIG. 91. Output network with unbalanced-to-balanced impedance transformation.

A high coefficient of coupling between the coils reduces the input shunt inductive reactance and also makes the network more broad-band. Baluns of this type are built as separate units for a 4:1 ratio of impedance transformation in the low-power range.

There are many advantages in using coaxial line within the transmitter building. The impedance is ideal for inserting additional harmonic suppression filters. This line eliminates r-f radiation near the transmitter, which is a great help in keeping r.f. out of the input circuits, control circuits, and power lines. In many cases, antenna switching can be done much more conveniently with a 50-ohm coax line switch than in a 600-ohm open-wire line.

FIG. 92. Dipole fed with shortened balun.

70. Shortened-line Balun. Many types of h-f antennas can be fed directly with a coaxial transmission line.[1] A dipole fed with a shortened balun for converting from an unbalanced line to a balanced antenna is shown in Fig. 92. The length l can be reduced from $\lambda/4$ to about $\lambda/10$ by tuning it to resonance with a capacitor. This coupling method has a band width of about 5 per cent.

71. Coil Balun. The band width of this type of balun can be increased by winding the shorted transmission-line section in the form of a coil as shown in Fig. 93. This presents a higher shunt reactance across the output over a wider frequency range. This coil balun has the advantage of being more compact which often is useful. It has the same impedance on both input and output terminals. The only difference is the unbalance-to-balance conversion.

72. Impedance-matching-line Balun. An impedance-matching balun is shown in Fig. 94. It uses the principle of the L network combined with a balun. The inductance, which determines the balun length, and the value of capacitance can be computed for the desired impedance transformation. This simple device is very useful, but its band width reduces with increasing values of impedance transformation.

73. Broad-band Impedance-matching-line Balun. A more broad-band impedance-matching balun employs several sections of transmission line with stepped values of impedance as shown in Fig. 95. This type of balun is useful over nearly a 4:1 fre-

[1] The balun transmission-line couplers discussed in this section are developments of the Collins Radio Company and have been described in its publications.

quency range.[1] The length l of each section is about $\lambda/4$ at the arithmetic mean of the highest and lowest frequency to be covered. This would be $\lambda/4$ at 12 Mc for covering the range of 6 to 18 Mc. The impedance of the transmission-line sections increases in geometric steps.
FIG. 93. Coil-type balun.
FIG. 94. Impedance-matching balun and equivalent circuit.
FIG. 95. Broad-band stepped-line balun.

74. Broad-band Impedance-matching Coil Balun. Another type of impedance-transforming balun uses coiled sections of transmission line as shown in Fig. 96. The parallel transmission lines may be coiled in either solenoid or spiral coil fashion. At one end the lines are connected in parallel, and at the other end they are connected in series. This results in a 4:1 impedance transformation. The coiled transmission lines pass balanced currents in the usual manner, but the coil inductance presents an impedance to unbalanced currents. For this reason, it can be rather successfully used with unbalanced as well as balanced input.

75. Broad-band 50- to 600-ohm Transmission-line Coupler. Figure 97 shows a broad-band unit for coupling a 50-ohm coaxial line to a balanced 600-ohm open-wire

[1] Fubini, Eugene G., and Peter J. Sutro, A Wideband Transformer from an Unbalanced to Balanced Line, *Proc. IRE*, **35**, 1153, October, 1947.

line. Units of this type have been built that can cover the entire 2- to 30-Mc range at power levels of a few kilowatts. It uses three coiled transmission-line sections to produce a 9:1 impedance transformation. A coil balun is used for a more perfect unbalance-to-balance conversion. The capacitors cancel some of the shunt inductance of the coil balun and the impedance-transforming coils at the low end of the frequency range. In practice, these are shunted with r-f chokes to keep the entire system grounded.

FIG. 96. Impedance-transforming balun.

This type of coupler is useful in coupling a transmitter with a 50-ohm output impedance to broad-band antenna systems, such as rhombics.

TRANSMITTER PERFORMANCE AND METHODS OF MEASUREMENT

76. Standards. The radio-station licensing authority, such as the FCC in the United States, establishes certain performance requirements. A few requirements, such as frequency tolerance, are established by international treaty. In addition to the basic requirements of frequency tolerance, power output, types of emission, band width, and carrier-frequency assignments, the FCC has published Standards of Good Engineering Practice.

The Institute of Radio Engineers has a standing committee on radio transmitters which publishes definitions of terms and methods of measurements. These are generally accepted by the industry and form a common understanding of the terms used in describing transmitter performance and the meaning of certain measurements. The Electronic Industries Association also has publications which may establish standards of performance as well as methods of measurement.

FIG. 97. Broad-band 50- to 600-ohm transmission-line coupler.
Transmitter manufacturers generally publish performance specifications on their equipment. Usually these are minimum performance figures which the manufacturer will guarantee. In other cases they are nominal performance ratings. The following paragraphs will discuss some of the more general transmitter-performance requirements and how they are measured.

77. Power Output. Power output is generally considered to be that power which the transmitter delivers at its output terminals. It always refers to average power over an r-f cycle. When the term "peak output power" is used, it means the average power over one r-f cycle at the crest of the output envelope.

The power-output rating may be given in several ways. It may be a guaranteed minimum or it may be a nominal rating. A nominal rating may mean that the power output may deviate either way from nominal, depending upon operating conditions or operating frequency. Also, it could mean the licensed rating of a broadcast transmitter which may be called upon to deliver enough extra power to overcome transmission-line and antenna-matching losses.

When a transmitter is designed to be operated on any frequency within a wide range of frequencies, there is some frequency that is least favorable to the transmitter. It may be low gain in some stage or higher tank-coil heating or any of a number of other factors. For this reason, the transmitter usually is tested for power output at this frequency and several others also. This frequency is usually at the maximum output frequency, but it may occur on the low end of the highest-frequency band or at some other frequency.

The transmitter may deliver power to certain load impedances more efficiently than to others. The power output is measured when feeding the nominal load impedance such as 52 ohms unbalanced or 600 ohms balanced with a unity standing-wave ratio, unless otherwise specified. There are numerous methods of measuring power. One basic standard is the calorimetric method. The r-f power output is dissipated in a resistive load which is liquid-cooled. The power is computed from the rate of flow of the cooling liquid and its temperature rise. When the cooling liquid is water, the power output in watts is

$$\text{Power} = 264Q\,\Delta t$$

where Q is water flow in U.S. gallons per minute and Δt is the difference between the inlet and outlet temperature in degrees centigrade. This method has the advantage that the exact impedance characteristics of the load need not be known. It can be used at any r-f frequency. The test setup must keep the heat loss or absorption from other sources, such as by conduction or radiation, to an acceptably low value.

R-f power in the low-frequency range is often measured by using a calibrated r-f ammeter in series with a known load impedance. The power is I^2R, where R is the equivalent series-resistance component of the load.

R-f loads are available for terminating coaxial lines in their characteristic impedance. Some include a meter calibrated in power. These instruments are usually r-f voltmeters calibrated in power since the load resistance is fixed.

Directional wattmeters are available for much of the r-f range. They are designed to be used in coaxial or wave-guide transmission lines and measure forward and reflected power. The real power is the difference of these readings.

There are also several substitution methods of measuring r-f power. These use a-c power to heat the r-f load the same amount as the r-f power heated it. Instruments are available for measuring the a-c power accurately, which determines the r-f power.

Transmitters which produce a type of emission that uses a carrier (*e.g.*, a.m., p.m., or f.m.) are rated in unmodulated carrier power output. The power output of an a-m transmitter is 150 per cent of carrier power when 100 per cent sine-wave modulation is applied. The peak power output is four times carrier power since both voltage and current are doubled at the modulation crest. Some a-m transmitters are not rated for continuous 100 per cent modulation. In many classes of service, the average modulation is quite low so the continuous modulation capability may be rated at some value such as 30, 50, or 70 per cent modulation.

Telegraph transmitters designed for on-off keying are not always rated for continuous key-down operation, since the key-down time seldom exceeds 50 per cent in normal transmission. When FSK is used, the power-output capability must be for continuous key-down output, however.

SSB transmitters are rated in peak envelope power output. A standard test signal of two equal-amplitude frequencies usually is used. The average power output, which can be measured by the calorimetric method, is one-half the peak envelope power, if there is no distortion present. The error due to distortion usually is neglected, since the average power measurement measures signal power quite accurately even though this may differ slightly from one-half peak envelope power. Peak-reading vacuum-tube r-f voltmeters usually have a fairly long time constant so they can be used across a known load resistance to measure peak envelope power directly. The time constant of the detector in directional wattmeters usually is very short; so it measures the average value of the current and voltage over the SSB envelope which

produces a reading of just 0.9 of the actual rms output power. For example, a 900-watt directional wattmeter reading for a two-frequency test signal indicates 1,000 watts of average power and 2,000 watts of peak envelope power. When one input frequency is removed and the other doubled in amplitude, the power output will be 2,000 watts, which will read correctly on the directional wattmeter.

The level of intermodulation distortion is very important in transmitters which multiplex voice channels. For this reason, the transmitter peak envelope power capability is sometimes established at the power level which produces a specified signal-to-distortion ratio such as 35 db.

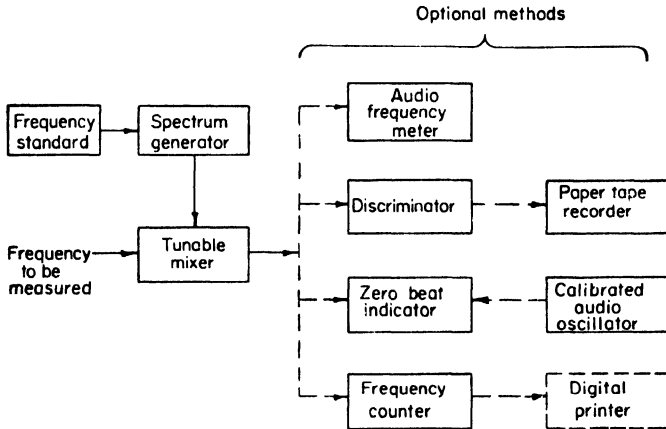
The average power output of an SSB transmitter with voice modulation is quite low. The size, weight, and cost of the transmitter power-supply and output network components can be reduced by taking advantage of this fact. Therefore, many


FIG. 98. Frequency-measuring apparatus.

SSB transmitters are rated for continuous operation with a two-frequency test signal but not for continuous single-tone output. Transmitters which will be used at maximum power for FSK or time-division multiplex must be rated for continuous power output, however.

78. Carrier-frequency Stability. Licensing authorities establish a tolerance within which the carrier frequency must be maintained. For example, m-f broadcast transmitters in the United States must be kept within ±20 cps of their assigned carrier frequency. A per cent tolerance such as 0.005 per cent is usually specified for transmitters in the h-f range and above.

Most transmitter specifications include the equipment performance capability with respect to frequency stability. This term is used to specify the ability of the transmitter to maintain a constant frequency. Such factors as variations in the power-source voltage, ambient temperature, relative humidity, or certain tuning conditions may affect carrier frequency. The maximum effect on frequency for specified amounts of variation is usually specified. In addition, aging may slowly change the carrier frequency. For this reason, frequency stability sometimes is given as having certain limits for a stated period of time, such as for a day or a month.

Frequency drift refers to the changes in average frequency during a specified interval of time. For example, this may refer to the change in frequency during the first few minutes of operation, or it may refer to aging effects over a long period of time.

79. Methods of Frequency Measurement. In one method, the radio wave is mixed with a standard frequency to obtain an output frequency which can be measured accurately and added to or subtracted from the standard frequency to obtain the frequency measurement. Figure 98 shows a block diagram of this type of apparatus.

The standard frequency is derived from a crystal oscillator usually operating at 100 or 1,000 kc. The spectrum generator employs frequency dividers, multipliers, and mixers to provide an output which contains a frequency at every 10-kc point across the spectrum of interest. These spectrum points have the same frequency stability as the standard oscillator. Its frequency can be checked against WWV by beating a spectrum point against a signal received from WWV. The crystal oscillator can be trimmed to zero beat.

A tunable mixer, which can be a receiver, selects the spectrum points nearest the frequency to be measured and mixes them, producing an output in the range of 0 to 5,000 cps if 10-kc spectrum points are used. This frequency can be measured and recorded by any of the four alternative methods shown. It must be determined whether the standard-frequency spectrum point is above or below the frequency of measurement, however. A button usually is provided on the crystal oscillator unit to change its frequency slightly in a known direction. Observing whether the beat frequency raises or lowers provides a means of establishing whether the beat frequency should be added to or subtracted from the standard-frequency spectrum point. The tunable mixer or receiver must be calibrated accurately enough to determine which 10-kc spectrum point is being used.

A paper-tape recorder is very useful for monitoring the frequency changes that occur during frequency-stability tests.

Another method uses a frequency counter directly. These instruments count the r-f cycles over a precise interval of time and display the resulting count. If the interval is 1 sec, the output reading will be directly in cycles per second. These instruments contain an internal standard oscillator which determines the accuracy of the time interval. An external standard-frequency source also may be used. Since the frequency range of counters is limited, some instruments contain a spectrum generator for converting the frequency to be measured down to the range of the counter. Instruments of this type are used for measurement of frequencies from audio to the u-h-f range. These instruments count for a set interval of time, display the count, and repeat this cycle continuously, if desired.

80. Audio-frequency Response. The a-f response of broadcast and voice-communication transmitters frequently is specified to be within a specified number of decibels over a given a-f range from the 1,000-cps response. For example, the response shall not vary more than ± 1 db between 50 and 7,500 cps from the 1,000-cps reference level. Another method merely requires the response to be within 2 db, for example, over the stated frequency range.

Communication transmitters usually limit the a-f response range. The attenuation of frequencies below some frequency in the range of 150 to 400 cps is used to permit a saving in the audio and modulator sections. This eliminates the low voice frequencies which contain much power but contribute little to intelligibility. The size of a modulation transformer is directly related to the lowest audio frequency it must pass at full power. The phase-modulator capabilities in an f-m transmitter also are directly related to the lowest audio frequency. The high audio frequencies are attenuated to limit the channel space occupied by the transmitter. Rapid attenuation of frequencies beyond 3,500 cps generally is required in voice-communication transmitters.

The response is measured at a sufficient number of frequencies to establish a frequency-response curve. A constant audio-input level is used for each frequency. The transmitter response is measured by a suitable detector, feeding an indicating instrument. A noise- and distortion-measuring instrument usually is used, which has a meter scale calibrated directly in decibels. The frequency response may vary a little with signal level, but it usually is measured at a moderate level such as 30 per cent modulation, unless otherwise specified.

81. Distortion. The distortion introduced by the transmitter generally means the rms value of all harmonics as a per cent of the fundamental test frequency. It may vary from less than 1 per cent for an a-m or f-m broadcast transmitter to 10 per cent

for a mobile voice-communication transmitter. The conditions under which distortion is measured are generally stated. A single test, using a 400- or 1,000-cps test frequency at 95 per cent modulation or at maximum deviation, may suffice. A complete test on a broadcast transmitter may require enough measurements to plot a curve of distortion vs. frequency over the entire a-f range. Distortion is usually greatest at maximum signal level, but sometimes data are taken also at lower levels.

A distortion meter generally is used for performing the distortion measurement. A suitable detector is used to demodulate the transmitter output signal. The instrument is adjusted to give the proper reference-level reading for the test tone. It is then adjusted to remove the test tone, leaving only the harmonics. Their level is then read directly in per cent distortion on the meter.
FIG. 99. SSB distortion products.

82. Signal-to-distortion Ratio. The principal type of distortion generated in SSB transmitters is intermodulation distortion. Signal-to-distortion ratio is the ratio of the amplitude of one frequency of two equal-amplitude test frequencies to a third-order distortion product. This ratio usually is expressed in decibels. Figure 99 shows the relationship of the distortion products to the two test frequencies f_1 and f_2. The inner pair of distortion products is called third-order products. They are spaced from f_1 and f_2 by the same amount f_1 and f_2 are spaced. The other products are fifth order, seventh order, etc., and all have the same spacing in frequency. The third-order products generally are strongest, although sometimes certain distortion-canceling conditions may exist in the transmitter which allow the fifth-order products to be greatest. A signal-to-distortion specification usually infers that all products are to be below the stated level.

The signal-to-distortion measuring instrument is a type of spectrum analyzer that has enough selectivity and frequency stability to select each frequency in the spectrum shown in Fig. 99 and measure its amplitude. A panoramic spectrum analyzer, which presents the spectrum of interest on the calibrated face of an oscilloscope tube, is an excellent measuring means, as all products are shown simultaneously.[1] The amplitude scale must be calibrated in decibels to obtain enough dynamic range, and this requires a logarithmic amplifier in the vertical deflection input circuit.

Signal-to-distortion specifications vary from 25 db for a single-channel low-powered voice-communication transmitter, where distortion is not important, to 40 db, where channels may be multiplexed and where out-of-channel emission must be kept to a low level. These distortion products are generated in the r-f power-amplifier stages,

[1] Icenbice, P. J., and H. E. Fellhauer, Linearity Testing Techniques for Sideband Equipment, *Proc. IRE*, **44**, 5917, December, 1956.

and the products of one channel may fall in another, creating an undesirable noise. This is more important than distortion of the signal itself.

83. Harmonic and Spurious R-f Output. As the number of transmitters and receivers increases, the probability of interference increases. Actually, interference is often most severe between various transmitters and receivers located in one station. Several h-f and v-h-f transmitters along with radar equipment may be operating simultaneously in one installation. A spurious output of one transmitter falling on the frequency of another signal being received can be serious. Some limits are being established for maximum spurious and harmonic output. These are being based on a fixed spurious output power limit so that higher-powered transmitters must incorporate a greater amount of spurious-signal suppression. For example, the maximum spurious-signal level expressed in decibels below the transmitter power for public-service transmitters approximately follows the formula 43 + 10 log power. The actual limits for various power ratings are given in a table, such as

	Db
Up to 3 watts	40
3–25 watts	50
25–150 watts	60
150–600 watts	70
Over 600 watts	80

The latest regulations and method of measurement should be consulted to determine the specific requirements for each case.

The output of a transmitter always contains some output at harmonics of the assigned frequency. The second harmonic is usually strongest, since the tank circuits provide greater attenuation of the next several higher-order harmonics. At still higher harmonic frequencies, the tank circuit may lose its effectiveness because of the stray capacitance across tank coils and the series inductance of capacitor elements. Also, resonances may occur at these frequencies so that harmonic output may be greater at the tenth or fifteenth harmonic than it is at some of the lower harmonics.

Other spurious frequencies depend upon the frequency-generating scheme. For example, a transmitter which uses frequency multipliers in its exciter may have an output on any harmonic of the fundamental oscillator frequency. Mixer-type exciters have many other spurious output possibilities which can be established by the chart in Fig. 8.

A signal-strength meter generally is used for making these measurements. The instrument must have adequate selectivity ahead of the first amplifier tube to prevent the generation of stronger harmonics in it than are being measured. The input level to the measuring instrument must be quite low; so a broad-band voltage divider is essential when measuring the output of a transmitter directly. A capacitance voltage divider coupled to the signal-strength meter by means of coaxial cable is usually most effective. The dummy load for the transmitter must present a constant impedance at all frequencies of measurement, if the measurements are to be meaningful.

Another method of measurement uses a signal-strength meter to measure the actual signal strength of undesired radiation. The transmitter may radiate some output directly besides that which is radiated by the antenna.

Undesired output may also be conducted out on the power-line and control-circuit connections. A separate measurement is necessary to determine the voltage of undesired outputs on these wires for a complete evaluation of all undesired transmitter output.

84. R-f Load Impedance. A transmission line usually is used to couple the transmitter to the antenna or to the antenna-matching unit. For this reason, the transmitter is required to match the specified transmission line with a certain range of standing-wave ratio permitted. An example is a 50-ohm line with up to 2:1 SWR. This means that this transmitter must be capable of matching any load impedance within the 2:1 SWR circle shown in Fig. 100.

85. R-f Envelope Observation. An oscilloscope set up for displaying the envelope of the transmitter output is a very useful test instrument. The r-f signal is coupled directly to the vertical-deflection plates by means of a tuned circuit and a coupling link to the transmitter. The linear sweep in the oscilloscope is used for observing most test signals. The keyed wave shape of a c-w transmitter can be observed directly. Its transient characteristics can be measured directly on the face of the oscilloscope. Also, the make-and-break characteristics which determine key clicks can be observed.

The modulation characteristics of an a-m transmitter can be observed in the same manner. The nature of appreciable amounts of distortion is readily apparent.

The envelope of an SSB transmitter with a two-frequency test signal will show the nature of large amounts of intermodulation distortion. Instead of using a linear sweep, a better observation can be made using an envelope detector for the horizontal signal. A trapezoidal figure results, and straight sides indicate low distortion. The envelope detector feeding the horizontal oscilloscope amplifier must receive its r-f input ahead of the principal source of distortion. A linearity tracer which uses two envelope detectors produces a plot of r-f input vs. r-f output of the amplifier under test. A straight line indicates low distortion. These observations are helpful in establishing proper operating condition and during "trouble shooting" but are not suitable for making measurements.

Fig. 100. Impedance locus of 2 to 1 SWR.

86. Primary Power Requirement. The nominal power-source voltage and power consumption are always given in transmitter specifications. A range of voltages may be given also, but unless the transmitter has an internal primary-voltage regulator, it should be operated as near the nominal design voltage as possible. Tube life is reduced greatly by high filament voltage. R-f power output may fall below its rated output at low line voltages. Best performance, along with long life and better reliability, will be obtained by providing a supply as near as possible to the design center value.

Alternating-current power requirements are expressed as watts with a stated power factor, or as volt-amperes. The power consumption for several operating conditions, including stand-by, may be stated. The installation wiring must be capable of delivering the maximum va or kva required by the equipment.

CHAPTER 19

RADIO RECEIVERS

By Charles E. Dean[1]

1. Classification. Radio receivers may be classified[2] according to their operating principles:

1. Tuned radio frequency.
2. Regenerative.
3. Superheterodyne.
4. Superregenerative.

Receivers of all these types have been made and used for amplitude-modulated (a-m) signals. For frequency modulation (f.m.) the superheterodyne is almost always used.

The following sections give general descriptions of these types, after which the various types and related topics will be discussed in detail.

Table 1. Designations of Frequency Bands by Abbreviations, Numbers, and Metric Classification of Wavelengths

Abbreviation	Meaning	Frequency range	Band No.	Metric designation by wavelength*
v-l-f	Very-low-frequency	3–30 kc	4	Myriametric waves
l-f	Low-frequency	30–300 kc	5	Kilometric waves
m-f	Medium-frequency	300–3,000 kc	6	Hectometric waves
h-f	High-frequency	3–30 Mc	7	Decametric waves
v-h-f	Very-high-frequency	30–300 Mc	8	Metric waves
u-h-f	Ultra-high-frequency	300–3,000 Mc	9	Decimetric waves
s-h-f	Super-high-frequency	3,000–30,000 Mc	10	Centimetric waves
e-h-f	Extremely-high-frequency	30,000–300,000 Mc	11	Millimetric waves

Other frequency band designations commonly employed are as follows:†

K band	30 kMc or 1 cm
X band	10 kMc or 3 cm
S band	3 kMc or 10 cm
L band	1 kMc or 30 cm
P band	1/3 kMc or 10 m

* In each band the wavelengths extend from 1 to 10 of the stated unit; *e.g.*, band 5 includes wavelengths from 1 to 10 km.

† The order in which these designations occur may be remembered by "*K*ing *X*erxes *S*educes *L*ovely *P*rincess."

Receivers for television service have various special features and are described in Chap. 22.

In the discussion of receivers in the present chapter, reference is often made to the various frequency bands by the abbreviations in Table 1.

[1] Hazeltine Research Corporation, Little Neck, L.I., N.Y.

[2] For an elementary treatment see Jordan, Nelson, Osterbrock, Pumphrey, and Smeby, "Fundamentals of Radio," edited by W. L. Everitt, Prentice-Hall, 1942; Keith Henney, "Principles of Radio," 6th ed., Wiley, 1952; David Grimes, "Meet the Electron," Pitman, 1944; M. G. Suffern, "Basic Electric Principles," 2d ed., McGraw-Hill, 1956. Certain general reference books containing material on various aspects of radio receivers, written for the design engineer, are listed at the end of this chapter.

2. Tuned-radio-frequency Receivers. Tuned-radio-frequency (t-r-f) receivers obtain their selectivity and r-f amplification solely through the use of selective circuits and tubes which function at the frequency of the incoming signal. This type has been largely replaced by the superheterodyne.

3. Regenerative Receivers. In a regenerative receiver, the received voltage is impressed on the grid of a vacuum tube; a portion of the resultant amplified voltage is fed back to the grid in the proper phase relation to increase the applied grid voltage. This action reduces the effective resistance of the resonant circuit where the signal is applied and thereby provides considerable amplification of the received signal.

The regenerative receiver is subject to the limitations that: (1) a critical adjustment of the feedback, just under oscillation, is necessary for substantial increase of sensitivity; (2) in adjusting the equipment more or less oscillation is likely, producing disturbance to other nearby receivers tuned to the same frequency; (3) the selectivity is sharp near the carrier and so may impair the audio quality; and (4) the employment of only a single tuned circuit results in inadequate rejection of interfering signals moderately removed in frequency. This type of receiver has therefore largely passed out of use.

4. Superheterodyne Receivers. In the superheterodyne the signal voltage is combined with a local oscillator voltage and converted into a new signal with the same modulation but a lower ("intermediate") carrier frequency, which is then amplified and detected to reproduce the original modulation.

The superheterodyne has the essential components of a t-r-f receiver, but in addition it has a frequency converter and an i-f amplifier. The frequency converter consists of an oscillator and a modulator. The oscillator and the t-r-f circuits are usually tuned simultaneously by means of a gang capacitor or a gang inductor. Constant frequency difference is maintained between the oscillator and r-f circuits, through the use of either (1) a combination of fixed shunt and series capacitors in the oscillator circuit in conjunction with a gang capacitor in which all the sections are identical, or (2) a gang capacitor in which specially shaped plates are used in the various sections, or (3) suitable arrangements of variable-inductance tuning.

The i-f amplifier in broadcast receivers generally uses two or three transformers, each containing two coupled tuned circuits. With this substantial number of circuits and the fixed and favorably chosen i-f value, the i-f amplifier provides the major portion of the amplification and selectivity of the receiver. Since the characteristics of this amplifier are independent of the frequency to which the receiver is tuned, the sensitivity and selectivity of a superheterodyne are usually fairly uniform throughout its tuning range. The r-f circuits are used primarily for eliminating certain forms of interference (especially image-frequency response) to which this type of receiver is subject.

The advantages of the superheterodyne make it the most suitable type for the great majority of radio services. It may therefore be considered the standard variety. For this reason numerous aspects of it are treated in the present chapter.

5. Superregenerative Receivers. A superregenerative receiver is a regenerative receiver in which sustained oscillations are prevented by the periodic variation of the effective resistance of the resonant circuit to which the received signal is applied.

In the superregenerator, oscillations are permitted to build up repeatedly in a resonant circuit tuned to the received signal. Sustained oscillations are prevented by the application of a quenching-frequency potential to the grid of the superregenerative tube. This potential periodically affects the tube characteristics in such a way as to stop the oscillations. The quenching frequency may be supplied either by a separate oscillator or by the superregenerative tube itself. If this frequency is in or near the upper part of the a-f range, the audio system of this type of receiver is usually provided with an a-f filter to remove the quench frequency from the audio output. An r-f stage ahead of the detector will prevent energy from being transferred from the superregenerative circuit to the antenna. A signal input of 50 to 100 μv will give an intelligible

signal although an input of 500 to 1,000 μv is generally necessary to reduce the noise to a satisfactory value. Harmonics of the quench frequency beating with the received signal make interference if the ratio between signal and quench frequencies is not 100:1 or more.

The superregenerator was used extensively to receive pulse-type signals in the v-h-f band during the Second World War and is of interest as a special type of receiver. It is discussed below, starting with Sec. 159.

6. F-m Receivers. During recent years, f.m. has come into extensive use in broadcast, police, military, and other services. The carrier frequency can be varied, if desired, over a wider range than the extent of the signal components. For example, in broadcast service in the United States a set of standards has been established by the FCC, under which audio frequencies to 15 kc are handled, but the maximum swing of frequency is ± 75 kc.

The usual broadcast f-m receiver is a superheterodyne differing in the following respects from m-f and h-f a-m broadcast receivers: (1) the carrier frequencies are much higher; (2) the band width is wider to accommodate the wide swing of the signal and the drift of the local oscillator; (3) the i.f. is higher, the present standard value being 10.7 Mc; (4) the i-f amplifier may contain one or more limiter stages; (5) the a-m detector is replaced by a frequency-sensitive device to reproduce the original audio wave; (6) the audio circuit contains a deemphasis circuit to remove the preemphasis inserted at the transmitter, this feature being another antinoise measure; and (7) the audio amplifier and speaker should be (but often are not) high-fidelity types to realize the high quality of which the system is capable.

METHODS OF TESTING

7. Characteristics Rated. Receivers are rated on the basis of numerous aspects of performance, including especially the following characteristics:

1. *Sensitivity* is that characteristic which determines the minimum signal strength to which the receiver will respond. It is measured quantitatively in terms of the input voltage or power required to give a standard output. Therefore, the receiver with the smallest value of this input is the most sensitive.

In the m-f and h-f bands the necessary input is usually stated in microvolts or in the corresponding number of decibels below 1 volt. For example, a set might have a sensitivity of 10 μv or 100 db.

The statement of sensitivity in terms of power is on the basis of *available power*, which is $E^2/4R$, where E is the open-circuit voltage of the signal generator in the sensitivity measurement and R is the resistance of the dummy antenna and the signal generator which together act as the source of signal supplying the receiver. The expression of sensitivity in terms of power is the usual practice in the higher-frequency bands.

2. *Noise* produced by a receiver, after defects such as hum, poor contacts, and faulty parts are corrected, comes from thermal noise in the antenna resistance and from noise originating in the tubes. Such noise is not large enough to be important in broadcast-band receivers having medium sensitivity and provided with an r-f stage, because high voltage gain in the first coupling network and first tube increases the signal to a value great enough to make all sources of noise small in comparison. Noise may be an important factor in the case of sets not having an r-f stage, and also in the case of all receivers requiring high sensitivity, such as automobile and farm sets.

In the v-h-f and higher ranges of frequency the input resistance of tubes is so low that the early circuits of the receiver cannot raise the signal voltage high enough to make the noise negligible. The amount of resistance noise and tube noise originating within the set is therefore important, and a quantity called the "noise factor" is used as a measure of this quantity. This is described in Sec. 19.

3. *Selectivity* is the degree to which the receiver is capable of differentiating between the desired signal and signals of other carrier frequencies. This characteristic normally requires one or more graphs for its expression.

4. *Fidelity* is the degree to which the receiver accurately reproduces at its output terminals the modulation possessed by the received wave.

5. *Maximum undistorted output* for a broadcast receiver is defined as the maximum power output which can be obtained from it when the output voltage does not contain more than 10 per cent of total harmonics.

Standard methods of testing receivers have been established by the IRE, covering broadcast receivers and to some extent receivers for other services. Various ones of these standards have been approved by the American Standards Association and therefore have the status of American Standards. The following is a current list of IRE standards[1] relating to receivers:

"Standards on Radio Receivers: Methods of Testing Amplitude-modulation Broadcast Receivers: 1948," 48 IRE 17S1 and ASA C16.19-1951.

"Standards on Radio Receivers: Definitions of Terms: 1952," 52 IRE 17S1, *Proc. IRE*, **40,** 1681, December, 1952.

"IRE Standards on Radio Receivers: Method of Testing Receivers Employing Ferrite Core Loop Antennas: 1955," 55 IRE 17S1, *Proc. IRE*, **43,** 1086, September, 1955.

"Standards on Radio Receivers: Methods of Testing Frequency-modulation Broadcast Receivers: 1947," 47 IRE 17S1 and ASA C16.12-1949.

Supplement to the above, "Tests for Effects of Mistuning and for Downward Modulation: 1949," 49 IRE 17S1 and ASA C16.12a-1951, *Proc. IRE*, **37,** 1376, December, 1949.

"Standards on Radio Receivers: Open Field Method of Measurement of Spurious Radiation from Frequency Modulation and Television Receivers: 1951," 51 IRE 17S1, *Proc. IRE*, **39,** 803, July, 1951.

"IRE Standards on Receivers: Methods of Measurement of Interference Output of Television Receivers in the Range of 300 to 10,000 Kc: 1954," 54 IRE 17S1 and ASA C 16.25-1955, *Proc. IRE*, **42,** 1363, September, 1954.

"IRE Standards on Methods of Measurement of the Conducted Interference Output of Broadcast and Television Receivers in the Range of 300 Kc to 25 Mc: 1956," 56 IRE 27S1, *Proc. IRE*, **44,** 1040, August, 1956.

"Standards on Railroad and Vehicular Communications: Methods of Testing: 1949," 49 IRE 16S1, *Proc. IRE*, **37,** 1372, December, 1949.

"Standards on Electron Devices: Methods of Measuring Noise: 1953," 53 IRE 7S1 and ASA C 60.13-1954, *Proc. IRE*, **41,** 890, July, 1953.

"American Recommended Practice for Loudspeaker Testing: 1942," IRE 6S1 and ASA C 16.4-1942.

"Standards on Audio Techniques: Definitions of Terms: 1954," 54 IRE 3S1, published in *Proc. IRE*, **42,** 1109, July, 1954.

"Standards on Television: Methods of Testing Television Receivers: 1948," 48 IRE 22S1 and ASA C 16.13-1949.

The following paragraphs give some of the essentials of the methods specified in these standards.

8. Definition of Terms.

1. *Sensitivity, selectivity, fidelity,* and *maximum undistorted output* were defined in Sec. 7.

2. *Normal Test Output.* An a-f power output of 0.5 watt in a standard dummy load connected across the output terminals of the receiver is the normal test output of a home receiver. This value applies unless the limited maximum undistorted output of the receiver qualifies it for one of the smaller values of normal test output given in Table 2. For automobile receivers, however, the value is 1.0 watt.

Table 2. Normal Test Output for Various Classes of Receivers

Max Undistorted Output, Watts	Normal Test Output, Watts
1 or more	0.5
0.1 or more but less than 1	0.05
Less than 0.1	0.005
All automobile receivers	1.0

[1] Also available is Publication 69 of the International Electrotechnical Commission, "Recommended Methods of Measurement on Receivers for Amplitude-modulation Broadcast Transmissions," 1954; sold at $3 by American Standards Association, 70 East 45th St., New York 17, N.Y.

Normal test output is also called standard test output.

3. *Sensitivity-test Input.* This is the rms r-f voltage, modulated 30 per cent at 400 cycles, which results in normal test output at resonance. It is applied through a standard dummy antenna.

4. *Selectance* is the selectivity against interference on a definite channel near the one to which the receiver is tuned. As shown in Fig. 1, it is expressed in decibels, or it may be given as the corresponding voltage ratio. The selectance against the next channel (10 kc from resonance) is also called the adjacent-channel attenuation (ACA), and against the next channel beyond (20 kc from resonance) is called the second-channel attenuation
FIG. 1. Definition of selectance and band-width values on typical selectivity curve of a complete receiver.

(SCA). The values should be averages of the decibel figures for the particular frequencies above and below the resonant frequency, or the corresponding voltage ratio obtained by taking the geometric mean of the two observed voltage ratios. Notation to designate each observation has been established, S_{+1} representing the selectance for the first channel above the tuned frequency and S_{-1} the first channel below. The letter S_1 represents the mean value computed as described. Likewise S_{+2}, S_{-2}, and S_2 represent values of the SCA.

5. *Band width* is another means of expressing selectivity and is used extensively. It is the total width of the frequency band at the edges of which the attenuation has a specified value. In many laboratories the notation W_6, W_{20}, W_{40}, and W_{60} is used to represent the band width at 6, 20, 40, and 60 db, respectively.

9. Receiver Test Equipment.

1. As a source of voltages for testing, a signal generator is necessary. This is a shielded oscillator whose frequency, for testing a-m receivers, can be varied over the range of carrier,

intermediate, and image frequencies of interest. Often provided is the range from 100 to 30,000 kc. Should it be desired to make fidelity measurements, an a-f oscillator is provided to modulate the r-f oscillator by a known amount at any frequency from 30 to 10,000 cycles. For most tests 400-cycle modulation is used. A calibrated attenuator is provided to furnish a range of outputs from 0.3 μv to at least 100,000 μv and preferably to 2,000,000 μv (from 130 db below to a preferable value of 6 db above 1 volt).
FIG. 2. Construction, use, and impedance characteristics of standard dummy antenna representing open antennas for broadcast reception in the m-f and h-f bands.

For the v-h-f and higher ranges, special signal generators are required. For the f-m broadcast band of 88 to 108 Mc, the feature of f.m. is, of course, necessary in addition to a suitable range of carrier frequencies.

2. *Standard Dummy Antenna.* The standard dummy antenna for a broadcast radio receiver is shown in Fig. 2, which is taken from the 1948 IRE receiver standards. It simulates typical actual outdoor antennas from 150 to 30,000 kc. The resistive and reactive components of the impedance are shown, as well as the modulus, which is the square root of the sum of the squares of the two components. At the higher frequencies the reactance can be seen to become negligible and the resistance and impedance magnitude to approach a value of 400 ohms, which is representative of unbalanced broadcast antennas in this frequency range.

For automobile receivers, dummy antennas of various types have been used. If the set is intended for a particular car and antenna, a dummy representing those conditions should be devised and used. One general dummy design consists of 7 ohms in series with 160 μμf, the latter shunted by 80,000 ohms. Another design consists of 100 μμf in series with 20 ohms. Another is merely a 40-μμf capacitor.

For sets with built-in loop antennas, the usual source of test signal is a fixed loop producing the test field. This is described in Sec. 10.

For the higher frequencies special cable matching the generator output circuit is desirable.[1] Also attention to the balanced or unbalanced relation to ground of generator and receiver may be needed, especially if the simultaneous use of more than one signal generator is involved.[2] Television and f-m broadcast receivers normally receive signal from a balanced 300-ohm transmission line. The dummy antenna for these cases is therefore a 300-ohm resistor, of which the signal generator will furnish a part. The resistance added in the circuit as the dummy antenna is ordinarily divided into two equal parts, one connected to each high terminal of the receiver.

3. *Standard Dummy Load.* This is a pure resistance equal to the 400-cycle impedance of the voice coil of the loud-speaker supplied with the receiver. The load resistor should be capable of dissipating the maximum power output of the receiver without an appreciable change in resistance.

4. *Harmonic-measuring Circuit.* For this purpose a harmonic analyzer capable of measuring frequencies up to 10,000 cps can be used. The instrument should have sufficient selectivity to separate each harmonic and should give the amplitude of each within an accuracy of 5 per cent. However, in normal practice, test equipment is generally used by which a composite test is made evaluating the total harmonic content as a single figure.

[2] Rankin, J. A., Receiver Input Connections for U-H-F Measurements, *RCA Rev.*, **6**, 473, April, 1942; the observations were made at 43 Mc.

10. Sensitivity Test. The sensitivity of a receiver designed for an open antenna is determined by impressing an r-f voltage of 400-cycle 30 per cent modulation in series with a standard dummy antenna and adjusting the intensity of the input voltage until normal test output is obtained at resonance for various carrier frequencies.

A receiver provided with an air-core loop antenna is tested by introducing signal inductively from a coaxial coil fed by the signal generator, or by introducing the test voltage conductively in series with the loop antenna. With the driving coil, which is the usual method, the field strength at the loop antenna is

$$E = 18.85NA^2 \frac{I}{X^3}$$

where E = equivalent electric field intensity, μv per m
N = number of turns in driving coil
A = radius of driving coil, cm
I = current in driving coil, ma
X = distance between centers of driving coil and loop antenna, m

The value of X should be at least twice the maximum dimension of either the driving coil or antenna, and much less than the distance to surrounding objects, such as the walls of the screened room.[1]

In the frequent cases of a ferrite-core loop antenna, the point to be considered the center of the receiver loop may be uncertain. For this and other reasons a modification of the air-core-loop procedure was adopted by IRE in 1955 and the standard embodying this is listed in Sec. 7. In this procedure the coaxial arrangement of the two loops is replaced by an arrangement in which the two axes are parallel; in particular, the center of the ferrite core is placed in the plane of the transmitting loop at a distance of 24 in. Other conditions are specified to remain the same, with the result that the field strength at the receiving loop in microvolts per meter can be taken as $\frac{1}{20}$ of the indicated output voltage of the signal generator; or in decibels, the field strength expressed in decibels below 1 volt per m is 26 db below the generator output expressed in decibels below 1 volt. A check to ascertain if the screen room being used is large enough to give free-space conditions, or to determine the necessary corrections of data, is recommended.

Detector sensitivity is a measure of the sensitivity of that part of the receiver including the detector and the audio amplifier. It is expressed in decibels below 1 volt, or as the equivalent fraction of 1 volt, and states the input of modulated i-f voltage necessary for normal test output. It is often desirable to obtain the result indirectly by measuring the sensitivity on the last i-f grid and correcting this value with the separately measured gain of the last i-f stage.

11. Selectivity Test. Selectivity is determined by tuning to the test frequency, observing the sensitivity, and then, with the receiver adjustments undisturbed, measuring the r-f input signal necessary to give normal test output at other frequencies. Points usually recorded are the discrimination at ±10 and ±20 kc (which are called *selectance values*) and the band width at 6, 20, and 60 db. In most cases it is not necessary to disable the a-v-c system because the levels at the output of the receiver and at the detector are constant, whence the a-v-c bias is constant.

In this determination of selectivity, only one frequency is applied to the receiver while each observation is made, and the test is therefore sometimes called the *single-signal* method of measurement of selectivity. It affords a measure of the rejection of unwanted signals by the frequency discrimination of the tuned circuits of the receiver, but it gives no information on effects which interfering signals can produce as a result of nonlinear tube characteristics or a result of the interference influencing the magnitude of the a-v-c bias. The term "effective selectivity" is sometimes used to indicate the over-all ability of a receiver to resist interference.[2]

[1] Practical procedures and designs of driving coils for testing air-core-loop receivers can be found in W. O. Swinyard, Measurement of Loop-antenna Receivers, *Proc. IRE*, July, 1941, p. 382.

[2] "Recommendation No. 95," Documents of London Assembly of International Consultative Committee on Radio ("CCIR"), I, 105–117, 1953. Sturley, K. R., "Radio Receiver Design," Part II, pp. 272–278, Wiley, 1945.

Tests of effective selectivity can be made by the use of two signal generators, one to represent the desired signal to which the receiver is tuned and the other to represent the interference. The 1948 IRE standards, listed in Sec. 7, include the single-signal selectivity test and also three two-signal tests, these being, respectively, for cross talk interference, whistle interference, and blocking interference. *Cross-talk interference* is manifested by the transfer of modulation on the undesired carrier to the desired carrier; this is caused by the nonlinearity (or overloading) of an early tube of the receiver and consequent modulator action. *Whistle interference*, consisting of "tweets," can be thought of as resulting from interaction between harmonics of the undesired carrier and of the oscillator of the receiver; they are further discussed in Secs. 50 to 52. *Blocking interference* acts by way of the a-v-c system or by overloading to cause the desired-signal output of the receiver to depend on the interference, the effect being ordinarily to reduce the output of the desired signal.

12. Electric Fidelity Test. This is determined by tuning the receiver to 1,000 kc, maintaining the input at 5,000 μv and 30 per cent modulation, varying the modulation frequency from 30 to 10,000 cps, and taking readings of relative output voltage at convenient modulation frequencies. The results at various a.f.s are expressed in terms of the value at 400 cps, which is taken as zero decibels or 100 per cent.

If the receiver has one or more tone controls, the test should be made with settings of the tone controls which will give maximum and minimum response at high and low frequencies.

13. Tests of Image Rejection and I-f Rejection. The ability of a superheterodyne to suppress the undesired image signal is measured as in the sensitivity test except that the signal generator is adjusted in frequency to deliver the image signal. This value of image sensitivity is then compared with the regular sensitivity to compute the image rejection, which is expressed in decibels or as a voltage ratio.

Any superheterodyne is more or less subject to interference from a station transmitting on or near the i.f. of the set. The receiver is tuned to the r.f. of interest and the signal generator to the i.f., *e.g.*, 455 kc. In this way the i-f sensitivity is measured. The i-f rejection is obtained by comparison with the normal sensitivity for the particular r.f.

Tests of other spurious responses are described in Sec. 52.

In the case of f-m receivers, the sensitivity to i-f interference at the antenna terminals of the set is usually measured with an f-m signal of $\pm$22.5-kc swing varying at a rate of 400 cps. The use of f.m. for the test signal determines the ability of the front-end circuits of the receiver to reject this spurious signal and avoids the test result depending on the behavior of the detector and the limiter, if any. Further treatment of tests on f-m receivers is given in Sec. 22.

14. Maximum Undistorted Output. This is determined by increasing the output in successive steps and measuring both the power output and the percentage of harmonics. The maximum undistorted output is the least power output which contains a total rms harmonic voltage content of 10 per cent of the fundamental voltage.

15. Maximum Output and A.V.C. For the maximum output the manual volume control of the receiver is set at maximum and a 1,000-kc signal with 30 per cent 400-cycle modulation is applied in increasing intensity. For open-antenna receivers the range of input signal is from 120 to zero db below 1 volt (1 μv to 1 volt). With air-core-loop receivers the observations are similar except that the intensity is in microvolts per meter and the maximum obtainable with the usual laboratory equipment is 200,000 μv per m, or 14 db below 1 volt per m. For ferrite-loop receivers the upper limit of observation is 100,000 μv per m, or 20 db below 1 volt per m. The output using either open or loop antenna is plotted as a curve. According to latest practice, additional curves are taken with zero, 10, and 80 per cent modulation.

To show the a.v.c., 30 per cent modulation is used and the manual volume control is reduced so that the power output for maximum signal input is $\frac{1}{10}$ to $\frac{1}{2}$ the largest value in the preceding tests. Again input signals over the full range of intensity are applied and a plot made of the observed output. A superior a-v-c system gives a

curve which, with increasing signal intensity, rises rapidly at low intensities and is then relatively flat over the medium and high range. The a-v-c figure of merit is defined as the reduction of the signal below a certain reference level for which the output declines only 10 db. For receivers intended for a wide range of signal input voltages (such as home receivers using open antennas), the reference level for determining the a-v-c figure of merit is 20 db (100,000 μv). For loop-antenna sets it is 26 db below 1 volt per m (or 50,000 μv per m). For receivers or tuning ranges primarily intended for small values of signal input, such as automobile receivers and the h-f bands of broadcast receivers, this reference level is 46 db (5,000 μv).

16. Hum Tests. Hum originating in a-f circuits is called "residual hum" and is measured with no r-f input to the detector. The i-f amplifier is disabled by shunting $\frac{1}{10}$ μf from the last plate to ground. Measurements are made with the volume control at its lowest and highest positions. In case there is a maximum of hum at an intermediate setting of the volume control, a measurement is made here also. The tests are normally made with an output voltmeter and may be computed and recorded in microwatts.

However, if the disconnected speaker shows apreciable hum voltage at its terminals, because of the presence of hum fields, the measurement should be made in terms of speaker current with the speaker normally connected; in this case the current-measuring equipment should not appreciably disturb normal relations in the circuit.

Hum produced by modulation of the carrier in the receiver is called "modulation hum" and is measured if it is several times as great as the residual hum. Values of modulation hum smaller than this cannot easily be measured with sufficient accuracy to be useful. For measuring modulation hum, signals at 1,000 kc of 50, 5,000, 100,000, and 1,000,000 μv and of 400-cycle 30 per cent modulation are applied, with the volume control adjusted at each signal intensity to give approximately the maximum undistorted output. At each signal intensity the observations consist of noting the audio voltage with the 30 per cent 400-cycle modulation and then switching off the modulation and noting the voltage of each hum component. The results are converted to per cent modulation by taking the ratio of hum-component voltage to 400-cycle voltage and multiplying by 30. For example, if the voltage of a particular hum component is 0.1 volt and the 400-cycle voltage is 1.0 volt, the noise modulation for this hum component is 3 per cent.

A simplified single measurement of either residual or modulation hum is often made by observing the effective total of all hum components. In this way a single power or a single hum-modulation-percentage value is obtained.

17. Tests Involving Noise. The 1948 IRE Standards include a measure of the amount of the random types of noise originating in a receiver. This is called "e.n.s.i.," standing for *equivalent noise side-band input*. The result is expressed in microvolts, or decibels below 1 volt, at the antenna terminal. Typical values for open-antenna receivers of the home and automobile types exceed 110 db. For such home receivers operating in the m-f band, with an r-f stage and typical antenna-coupling voltage gain of 15 to 18 db, the e.n.s.i. normally amounts to 121 to 123 db. Automobile receivers with antenna voltage stepups as high as 26 db have typical e.n.s.i. of 132 to 137 db. An open-antenna home receiver without an r-f stage has increased noise because converter tubes are more noisy than amplifier tubes, and such a set may be expected to have an e.n.s.i. of about 117 db.

The significance of e.n.s.i. may be appreciated when it is noted that satisfactory reproduction of a broadcast program for the average listener requires a signal-to-noise ratio of 40 db, and mediocre reproduction requires a ratio of 20 or 25 db. For example, a set with an e.n.s.i. of 117 db requires for satisfactory reproduction a signal strength of 77 db, whereas a set with an e.n.s.i. of 137 db will give equally good reproduction on a much smaller signal, *viz.*, one of 97 db below 1 volt.

Another quantity describing noise performance is the *noise factor*. This has come into wide use, especially for receivers operating in v-h-f and higher frequency ranges. A discussion of noise factor is given in Sec. 19.

18. E.N.S.I. Test. The procedure for measuring e.n.s.i. is as follows: (1) select a convenient carrier of about 100 db below 1 v (10 μv) and call this $(E_s)_{db}$; (2) with this carrier applied without modulation, measure the rms noise voltage delivered by the receiver, calling this E_n'; (3) switching on 400-cycle 30 per cent modulation and inserting a 400-cycle band-pass filter in the output circuit of the receiver (which will remove practically all the noise), measure the rms 400-cycle output, calling this E_s'; (4) compute e.n.s.i. from the formula

$$(E_n)_{db} = (E_s)_{db} + \left(\frac{E_s'}{E_n'}\right)_{db} + 10$$

Example: Consider a set measured at 100 db and giving signal and noise outputs of 50 and 10 volts, respectively. The output signal-to-noise voltage ratio is 5, or 14 db. The e.n.s.i. is then 100 + 14 + 10 = 124 db.

If E_n and E_s are in microvolts and E_s' and E_n' in volts, the e.n.s.i. in microvolts can be obtained from the relation

$$E_n = 0.3E_s\left(\frac{E_n'}{E_s'}\right)$$

Example: To illustrate the application of this formula, consider the example just given. The value of E_s is 10 μv, corresponding to 100 db, and E_n'/E_s' is $^{10}/_{50}$ or 0.2, whence $E_n = 0.3 \times 10 \times 0.2 = 0.6$ μv, which is the same as 124 db.

E.n.s.i. is an indication of the amount of thermal and tube noise referred to the antenna terminal. It is not intended to show the amount, or the presence, of other types of disturbance, such as hum, atmospherics, or noises due to faulty operation. It is not important with insensitive sets because they have insufficient amplification to build up the thermal and shot noise to appreciable magnitude. The significance of the name "equivalent noise side-band input" is this: a single side frequency 400 cycles removed from the carrier and having this (e.n.s.i.) strength would produce an rms output of 400 cycles just equal to the rms value of the noise output produced by the receiver. The normal a-m signal has an upper side frequency and a lower one with such phase relations that in the detector the audio voltage due to the beating of the upper side frequency with the carrier adds to the audio voltage due to the beating of the lower side frequency with the carrier; *i.e.*, the total audio power of E^2/R is quadrupled in comparison with the value it would have if only one side frequency were present. However, with noise the side frequencies are random in phase, with the result that the audio output from components of higher frequency than the carrier adds in terms of power to the output from components of lower frequency, a doubling rather than a quadrupling of the power. With noise there is an absence of cooperation between the upper and lower side bands, and this result is represented by considering the e.n.s.i. to be a single side frequency.

E.n.s.i. and especially noise factor, which is presented below, have become matters of importance with receivers for the v-h-f and higher frequency ranges. One reason is the limited tube input impedances, because these limit the voltage gain which can be realized in coupling networks, with the result that the early coupling networks of the receiver cannot increase the voltage of a weak signal sufficiently to make it amply override the random noise produced in the early resistances and tubes of the receiver.

19. Noise Factor. The value of the e.n.s.i. of a receiver does not indicate directly whether the noise is large or small in comparison with an ideal receiver. For this reason, another measure of noise, called the "noise factor" or "noise figure" or "excess noise increment," has come into wide use, especially for receivers designed for the v-h-f, u-h-f, and s-h-f bands. This quantity, broadly speaking, gives a comparison between the actual noise output of the receiver and the smaller noise output which would be produced if the only source of noise were from the antenna resistance. Thus, the actual receiver is compared with an ideal having no internal sources of noise and reproducing only the noise originating in the resistance of the antenna. However, from a stricter

standpoint, the noise factor is independent of the audio-amplifier characteristics and of the total gain of the receiver. It is a measure of the noisiness of the receiver resulting from the introduction of noise in the early coupling systems and tubes.

The noise factor is expressed in decibels or as a power ratio; it is not customary to state it as a voltage or current ratio. The larger the noise factor, the noisier the receiver. Typical values range from 8 to 30 db. The noise factor is of interest with any receiver having sufficient gain so that the ability to receive weak signals is limited by the presence of noise originating in the receiver.

Before giving the precise definition of noise factor, it is advisable to describe *available power*. Any source of voltage having an open-circuit value E and associated with an internal resistance R will deliver maximum power to a load of matched value, *i.e.*, a load equal to R. The load voltage is then $E/2$, and the current is $E/(2R)$. The maximum load power is the product of this voltage and current and is, therefore, $E^2/(4R)$. This is called the *available power* from the particular source.

An actual or dummy antenna of resistance R can be shown to have an open-circuit rms thermal-noise voltage equal to $\sqrt{4KTRB}$, where K is a constant with the value 1.37×10^{-23}, T is the absolute temperature (usually taken as 290°), R is the resistance in ohms, and B is the total band width in cycles between the 3-db points. The available noise power is KTB. For the noise factor, all internal noise sources are referred to the input of the receiver in terms of power, and the noise factor is the ratio which the sum of this power plus KTB bears to KTB, expressed in decibels or as a power ratio. A perfect receiver reproduces only the noise of the antenna and has a noise factor expressed as a power ratio of unity, or zero decibels.

The noise factor of receivers designed for frequencies from the m-f range up into the u-h-f range can be conveniently measured with a temperature-limited diode, *i.e.*, one without space charge, as a noise source. The noise generator and dummy antenna are connected, but the noise generator is not yet turned on. An observation is made of the noise output power P_1 of the i-f amplifier under these conditions. Then the noise generator is turned on and its output is adjusted until the noise output of the i-f amplifier has increased to $2P_1$. The direct space current I of the diode (which is the means of adjusting the noise generator output) is then recorded. It can be shown that the noise figure of the receiver in decibels is

$$10 \log_{10} (20IR)$$

where R is the resistor through which the noise current flows. For example, with 0.040 amp and 70 ohms, the value of $20IR$ is 56, corresponding to 17.5 db.[1]

For receivers operating above 200 Mc, and especially above 1,000 Mc, a suitable noise source for measuring noise factor has been found in the fluorescent lamp. A noise output of 15 or 16 db above the resistance noise is furnished by these sources. Daylight types of lamps of 6 and 8 watts are useful, and also an argon lamp designated as the EIA 6357. For precise results in the 9,000-Mc region argon lamps are recommended with the bulb temperature held between 40 and 50°C.[2]

Noise sources such as those used for measuring noise factor are in some cases very convenient for determining the sensitivity of receivers because there is no necessity of tuning the generator for each frequency. The method, however, has the obvious limitations that the receiver band width must be uniform over the range of frequencies, and spurious responses, such as the image, should be small.

There are numerous refinements to which attention should be given in making noise-factor and other types of measurements on receivers operating in the v-h-f and higher frequency ranges. The use of wave guides, with their various "plumbing"

[1] For further treatment of noise factor, see H. T. Friis, Noise Figures of Radio Receivers, *Proc. IRE*, July, 1944, p. 419. Goldberg, H., Some Notes on Noise Figures, *Proc. IRE*, **36**, 1205, October, 1948; Moxon, L. A., "Recent Advances in Radio Receivers," pp. 1–19, 73–83, Cambridge, 1949. van der Ziel, A., "Noise," pp. 32–87, Prentice-Hall, 1954.

accessories, and numerous other techniques not employed at lower frequencies gives a special character to measurements of receivers for microwave use.[1]

20. Measurement of Interference Produced by Receivers. In common with other electrical appliances, receivers can produce unwanted output which interferes with reception at other receivers. Methods of measuring interference from appliances[2] are therefore applicable to receivers, but for the most important cases special measuring equipment and procedures have been developed.

Interference produced by receivers has been most serious in the v-h-f and lower u-h-f bands and has led the FCC to set up the requirement that, after certain dates, receivers for all or any portion of the range from 30 to 890 Mc must be certificated as to compliance with certain definite requirements in this connection, as discussed below. These requirements include (1) sufficiently low radiation of interference at any frequency from 25 to 1,000 Mc, and (2) sufficiently low interfering voltage delivered to the power-supply line at any frequency from 0.450 to 25 Mc.[3]

The first one of these two requirements is of interest in the design of f-m receivers for the broadcast band of 88 to 108 Mc. The amount of radiation is measured at a distance of 100 ft with various antenna heights and procedures in accordance with the IRE standard of 1951.[4] In particular, this specification requires the antenna of the

Table 3. Maximum Radiation at 100 Ft Permitted by Federal Communications Commission for Receivers Tuning to Any Part of Band from 30 to 890 Mc

Frequency of Interference, Mc	Maximum Field Strength, μv/m
25–70	32
70–130	50
130–174	50–150 (linear interpolation)
174–260	150
260–470	150–500 (linear interpolation)
470–1,000	500

receiver under test to be at an elevation of 30 ft, taken as a practical value and a compromise between the wide extremes of actual usage. The antenna used to pick up the radiation at 100 ft is initially at a height of 20 ft. The receiver under test and its antenna, both mounted on a turntable, are then rotated and the turntable stopped at the point of largest interference reading. The pickup antenna is then gradually lowered to a height of 7 ft, and the largest field strength found is recorded as the value of the radiated interference. Separate observations are made with horizontal and vertical positions of the pickup antenna so as to obtain data for both wave polarizations. These observations are made with the receiver under test connected normally to its antenna. To test for chassis radiation, the antenna of the receiver being tested is replaced by a 300-ohm noninductive resistor and the test procedure repeated. The highest of the four values (two polarizations for antenna connected and the same without the antenna) is entered as the radiation for the particular frequency setting of the receiver under test and the particular frequency at which the field-strength meter is set. Other frequency settings of the field-strength meter are then used, and then the measurements are repeated at other tuning adjustments of the receiver under test. In terms of the frequency of the interfering radiation, the values must not exceed the amounts shown in Table 3.

The measurement of interfering radiation requires a field-strength meter, which is a radio receiver of special design. These instruments are briefly described in Sec. 197.

21. Measures of Sensitivity Allowing for Noise. E.n.s.i. and the noise factor are measures of performance with regard to noise and do not give information as to receiver sensitivity. A need for a single quantity indicating performance with regard to both noise and sensitivity has been recognized for two decades or more in connection with military and naval receivers, and has led to the specification that the volume control of the receiver be reduced if necessary to avoid output noise exceeding a stated amount. The sensitivity of the set was then measured with this position of the volume control, and the result required to pass the sensitivity provision of the specifications. For example, in one of the armed services a receiver for headphone reception of voice was tested by adjusting the volume control to give an output of 600 μw of noise with carrier present but unmodulated. Upon application of standard 30 per cent 400-cycle modulation, the output was required to increase to 6 mw, corresponding to a signal-to-noise ratio of approximately 10 db. Some successive approximation in the test in this case is necessary until the proper volume-control setting and carrier level are found. This carrier level is then the measured sensitivity.

A slightly different procedure for obtaining a sensitivity measurement which takes noise into account has been proposed by J. M. Pettit.[1] He suggests that the quantity be called the *combined sensitivity figure*. Successive approximation is avoided by arbitrarily establishing in advance the standard noise output. With the signal generator and dummy antenna connected but the generator not operating, the volume control of the receiver is advanced until standard noise output is delivered. This setting of the volume control is thereafter not disturbed and is called the *standard gain setting*. The signal generator is then started and a regular sensitivity measurement made. This value is the combined sensitivity figure.

22. Testing F-m Broadcast Receivers.[2] The standard modulation is 30 per cent of the full 75-kc swing to either side, or ±22.5 kc. The a.f. remains at 400 cycles. The least value of carrier to give normal test output, which is the same as with a.m., is called the *maximum-sensitivity test input*, and the result of the measurement is said to determine the *maximum sensitivity*. (In television broadcast service the sound channel operates with frequency modulation, for which the full deviation is ±25 kc, so that the value for 30 per cent modulation, used in testing television receivers, is ±7.5 kc.)

Another test is made with the full 75-kc deviation. Starting with a very weak signal, the input signal level is increased and the volume control reduced, maintaining normal test output, until the output distortion, measured as the effective sum of all harmonic voltages, declines to 10 per cent. This is the *maximum undistorted output*, and the signal input at this point is said to determine the *maximum-deviation sensitivity*.

The *quieting sensitivity* is determined by the least unmodulated signal which reduces the internal receiver noise to the point where the test output rises 30 db when standard test modulation is applied to the input signal. That is, the quieting-sensitivity measurement determines the input necessary to give a 30-db signal-to-noise ratio upon the application of the standard 400-cycle 22.5-kc-deviation modulation. The receiver is adjusted for greatest sensitivity except that the volume control may be reduced to prevent audio overload. This test shows the relative freedom of the receiver from noise noticeable during pauses in the program.

These three values of sensitivity are expressed in terms of input signal. It is usually considered that the poorest one of the three determines the usefulness of the receiver.

A fourth test determines the *deviation-sensitivity input*, which indicates the amount of deviation necessary for standard test output at standard mean-signal input. The

result of this test is expressed in kilocycles deviation, *e.g.*, 5 kc, indicating a swing of this much in each direction. The test shows whether the useful sensitivity of the receiver is limited by the audio gain. The standard mean-signal input is an available power of 90 db below 1 watt, or 1,100 μv acting through a 300-ohm dummy antenna. (For the sound channels of television receivers this test is made at a signal level of 3,200 μv.)

Observations with various dummy antennas have shown the most reliable measurements on balanced-input receivers to be obtained with a signal generator having balanced-output connections and a dummy antenna consisting of 600-ohm resistors connected to each high lead of the generator, the other ends of these resistors being joined through a 400-ohm resistor. The receiver is connected across the 400-ohm resistor, and the grounds of the signal generator and receiver are connected. Each of the 600-ohm units includes the internal resistance of one side of the signal generator, so that they must actually be somewhat less to give a 600-ohm total. If the common ground connection between the generator and receiver chassis is removed, good results are still obtained.

A simpler dummy antenna for a balanced generator consists only of two 150-ohm resistors, including the generator resistance. This gives good results if the grounds of the generator and receiver are *not* connected.

For unbalanced generators, satisfactory results are obtainable with two 150-ohm resistors, reduced as necessary to give a total of 300 ohms for the generator and the two resistors in series. It is necessary to avoid a direct connection between the grounds of the two chassis.

Two precautions have been suggested[1] in this regard: (1) the polarity of the generator output should be reversed, and (2) the power-line connection for either the generator or the receiver should be moved to a different outlet. No change in the measured sensitivity of the receiver should result from either of these two changes.

23. Typical Performance. The performance of broadcast receivers for the standard broadcast band has remained much the same while their size has been reduced by the

Table 4. Representative Characteristics of the Most Widely Sold Type of Receivers for the Standard Broadcast Band*

Characteristic	Value
Sensitivity, db below 1 volt/m	72

Maximum undistorted output, watts†	0.07–0.80

* Values are for operation at 1 Mc.
† Maximum undistorted output varies with type of output tube.

incorporation of miniature tubes, smaller versions of other parts, and the use of ferrite-core-loop antennas. The most widely used type of receiver has a ferrite loop and four tubes plus power rectifier, the four tubes being (1) the converter; (2) the i-f stage; (3) the detector, a-v-c, and first audio amplifier; and (4) the output audio stage. The performance of such a receiver is ordinarily about as given in Table 4. Receivers with a three-gang tuning capacitor and an r-f stage have materially better image and i-f rejections, while those with improved audio features, such as a push-pull output stage, larger output transformer, and larger speaker, afford improved fidelity and volume range of reproduction.

[1] Rankin, John A., Receiver Input Connections for U-h-f Measurements, *RCA Rev.*, April, 1942, p. 473. This gives data at 43 Mc.

The loop figure of merit, as described in Sec. 32, is stated in decibels. The fact that this is negative shows that a field strength of, for example, 1,000 μv per m produces less than 1,000 μv on the first grid.

The a-v-c figure of merit, as described in Secs. 15 and 79, is the change in input signal intensity below 50,000 μv per m necessary to produce a 10-db change in output.

The maximum undistorted power output, which is defined in Sec. 14, is the largest output which will not produce more than 10 per cent effective sum of harmonic voltages, corresponding to 1 per cent total harmonic power.

The converter sensitivity, i-f sensitivity, or the detector sensitivity is the number of decibels below 1 volt characterizing the signal that is just sufficient to produce normal test output.

NOISE IN RECEIVERS

24. Necessary Signal-to-noise Ratio. Signal and noise can be measured and compared in terms of rms voltage or current, or in terms of power, and the ratio of signal to noise expressed in decibels. For satisfactory reception of the typical broadcast program, a signal-to-noise ratio of 40 db is necessary. A value of 30 db has been established as determining the "interference test output" in certain standard receiver-test procedures. In television 30 db is about the minimum signal-to-noise ratio for a satisfactory picture. In radiotelephone service, where intelligibility is the chief criterion, 18 db is sufficient. Other service, such as radio direction finding, where the indications may be read on meters, will operate with much lower signal-to-noise ratios and may even function with less signal than noise corresponding to a signal-to-noise ratio expressed by a negative number of decibels.

Any one of numerous conditions can produce disturbance to radio reception. The cause may be external to the receiver, such as atmospherics, cosmic static, interference from unfiltered electrical appliances like elevators and shavers, ignition noise from automobiles, or interference from diathermy equipment. Internal noise can arise in the form of hum, hiss originating in early circuits and tubes of the set, and clicks or other disturbance from faulty connections, tubes, fixed capacitors, or other defective parts.

25. Sources of Noise External to Receiver. Every frequency used for radio operation is subject to interference from one or more of the following sources: (1) cosmic radiation coming from the heavens; (2) terrestrial "atmospherics" from near or distant lightning storms; and (3) man-made interference from electrical appliances of many kinds. At each receiver therefore a certain interfering level exists, and the strength of the desired signal must be sufficient in comparison to serve the required purpose. If this received signal-to-noise ratio is ample, the task of the receiver is easy; but if a marginal signal-to-noise ratio is expected or encountered, special features of system and receiver design should be considered for adoption. Such features are listed in Sec. 29 and discussed in other sections concerned with particular topics of receiver technology.

Many measurements by the National Bureau of Standards[1] can be summarized as follows: (1) By choosing suitable nonmetropolitan receiving sites, man-made interference can normally be kept below terrestrial and cosmic noise; (2) at such locations for frequencies below 15 Mc thunderstorms usually represent the principal source of noise; and (3) for frequencies between 15 and 150 Mc at such locations the noise is chiefly from cosmic sources, *i.e.*, of galactic and solar origin.

The magnitude of these external noise disturbances, as manifested in voltages picked up by an antenna, is substantial, especially at the lowest radio frequencies. With a short vertical antenna at 10 kc, plots such as Fig. 3 showed the voltage from atmospherics to be 120 to over 160 db above the resistance or thermal voltage of the antenna; *i.e.*, the antenna had an effective noise factor of this many decibels from the

[1] Crichlow, W. Q., D. F. Smith, R. N. Morton, and W. R. Corliss, Worldwide Radio Noise Levels Expected in the Frequency Band 10 Kilocycles to 100 Megacycles, *Nat. Bur. Standards Circ.* 557, 1955; for sale by Superintendent of Documents at 30 cents.

atmospherics. At higher frequencies the curves decline in more or less straight lines to the region of a few megacycles. Other plots similar to Fig. 3 show considerable variation for other times of the day and of the year, the values for 2 Mc lying between zero and 84 db with an average of 48 db for the curves for medium (No. 3) noise grade. Between 10 and 30 Mc the curves fall off steeply and pass under the line for galactic noise.

The lines for man-made and for galactic noise are seen to constitute almost a single straight line from 82 db at 100 kc to 7 db at 100 Mc. These noise sources vary little with time of the day and year.
FIG. 3. Median values of atmospheric, galactic, and man-made noise expected for the hours 4 to 8 A.M. in winter, using a vertical antenna. (*From Crichlow, Smith, Morton, and Corliss, Nat. Bur. Standards Circ.* 557, 1955.)

Sources of man-made noise are very numerous, including sparking motor commutators, transmitters radiating harmonics of the assigned frequency or subharmonics coming through from the premultiplication stages, improperly controlled or shielded h-f equipment in industrial or medical service, etc.[1] Legal control of such interference has long been established in Canada[2] and more recently in the United States.

The usual methods of curing interference due to appliances[3] are (1) to connect a low-pass filter in the supply line as close as practicable to the appliance, so as to prevent the line from acting as a conductor or antenna for the interference, (2) to connect capacitors at sparking elements of appliances such as motor brushes, and (3) to locate the antenna where the noise is not encountered and use a leadin having a balanced arrangement or shielding, or both. Assembled power-line filters for various applications are offered by firms manufacturing fixed capacitors.

Automobiles and trucks will produce interference over a wide frequency range

if not provided with suppression devices such as are often installed to permit radio reception on the vehicle.

Ignition interference is an example of *impulse noise*, which is to be distinguished from fluctuation noise. Impulse noise consists of discrete separate pulses with relatively long quiet intervals between. Each pulse shock-excites the usual radio tuning circuits. The resulting oscillations have the frequency of the various tuned circuits and die out exponentially; *i.e.*, each disturbing pulse produces a damped train of oscillations. Ordinarily, this train dies away considerably before the occurrence of the next pulse. Fluctuation noise, on the other hand, is always present with an instantaneous amplitude determined by statistical probability laws. Examples of it are resistance noise and tube noise, mentioned below.

26. Noise Sources in the Receiver. After noise due to poor contacts, defective parts, and microphonics has been removed from a receiver, it will, with the usual a-c power supply, still deliver noise in the form of *hum.*[1] By good design and maintenance work, this can be reduced until it is no longer appreciable. Whenever hum is encountered, special attention should be paid to the low-level audio stages (where the trouble may be heater-cathode leakage), the possibility of inadequate plate-supply filtering, or magnetic induction from stray fields. Another type of this disturbance is "modulation hum," which is present only while a carrier is being received. This is produced by nonlinearity in the r-f and i-f stages plus a hum voltage, so that the hum modulates the carrier. Such hum would, of course, be reproduced by a perfect detector and audio system and must be corrected by removing the cause in the r-f or i-f amplifier.

Other noise sources in the receiver include those of the random-fluctuation type producing a characteristic hisslike sound in reproducers and "grass" on oscilloscopes. These sources include resistance noise and tube noise, important in high-gain receivers and in receivers for the v-h-f and higher frequency ranges.

27. Fluctuation Noise. The irregular motion of electrons in any resistor and in the space current of any tube gives rise to the fluctuation type of noise.[2] These random motions result in small fluctuations of voltage and current. The instantaneous value of this voltage or current obeys the probability law, under which there is a certain probability that the value will fall in any range of interest. For example, there is a very small probability that a very large value will occur, so that the usual concept of peak amplitude does not apply. Instead, the probability of a large amplitude increases as the band width of the equipment is increased. There is no definite wave form. However, there is a definite rms value and also a definite average value for all positive or all negative amplitudes. These two averages are equal and each amounts to 80 per cent of the rms value.

The instantaneous amplitude in one direction or the other exceeds the rms value 32 per cent of the time, but it exceeds four times the rms value for only 6.4/100,000 of the time.

Another characteristic of fluctuation noise, before it has gone through any selective circuits, is that it has a uniform frequency distribution; *i.e.*, a 1,000-cycle band selected in the audio region has as much rms voltage as a 1,000-cycle band at 1, 10, or 100 Mc.

Fluctuation noise establishes a limit to the amount of amplification that can be usefully employed. At the input to a receiver or amplifier, the signal must be large enough so that it will not be lost in the noise associated with resistances and tubes in the low-power portion of the equipment.

28. Thermal Noise and Tube Noise. The random motion of electrons, under the molecular agitation due to temperature, produces noise across the terminals of any

IRE*, **44**, 609, May, 1956, gives a substantial introduction to the theory of the subject. Bennett, W. R., series of five articles on various phases of noise, *Electronics*, **29**, as follows: 154, March, 1956; 134, April, 1956; 162, May, 1956; 154, June, 1956; 148, July, 1956.

resistor. A parallel resonant circuit or other passive network manifests the same effect to the extent corresponding to the resistive component of the impedance. The magnitude of the open-circuit rms voltage is given by the relation

$$E = \sqrt{4KTRB}$$

where K = Boltzmann constant = 1.37×10^{-23}
T = absolute temperature, °K (about 300 for room temperature)
R = resistance, ohms
B = band width, cps

For radio purposes it is more convenient to express this in microvolts, ohms, and megacycles. Making these changes and inserting the numerical values of K and T, we obtain

$$E = 0.13 \sqrt{RB}$$

Values of E for wide ranges of resistance and band width are plotted in Fig. 4.

For the usual noise computations, which have a limited accuracy, the determination of B will be easy. For a selectivity curve having a shape like that of a single tuned circuit, the value of B is the total frequency interval between the two points where the curve is 3 db down. For more involved cases, a graphical determination can be made by using graph paper with linear graduations in both directions and plotting frequency as abscissas and power (or voltage squared or current squared) as ordinates. Measure the area under the curve and determine the width of a rectangle of the same area having a height equal to the highest single ordinate. The width of this equivalent rectangle is the desired value of B.

An important quantity associated with the thermal noise voltage is the *available power* from such a source. As with any source of open-circuit voltage E acting through an internal resistance R, the maximum power which can be delivered, defined as the available power, is obtained by matching the load resistor to the internal resistance. The value of the available power is $E^2/4R$. Applying this to the case in hand, the available thermal-noise power is $(0.13)^2RB/4R$, or $W = 0.004B$. Here B is in megacycles, and W is in micromicrowatts. Table 5 gives values computed from this formula. An alternative expression for available noise power is 4×10^{-21} watt per cycle of band width.

Fluctuation noise originates in tubes due chiefly to (1) the random nature of emission at the cathode and (2) the irregular and changing distribution of current between plate and screen if the tube has a screen. The first of these was discussed by Schottky[1] in 1918, along with resistance noise, all under the name *schroteffekt* (German for "shot effect") from the similarity of the sound to that of many small pellets falling on a hard surface. During the years this term has come to be restricted by most workers to tube noise resulting from random cathode emission so that resistance noise is not included. The name "partition noise" is often applied to tube noise resulting from the irregularities in distribution of current between plate and screen.

Table 5. Available Power of Thermal Noise for Various Band Widths

Band width, B, Mc	Available power, W, $\mu\mu$w	Decibels below 1 watt
10^{-4} (100 cycles)	4×10^{-7}	184
10^{-3} (1,000 cycles)	4×10^{-6}	174
10^{-2} (10 kc)	4×10^{-5}	164
10^{-1} (100 kc)	4×10^{-4}	154
1	4×10^{-3}	144
10	0.04	134

A common method of stating tube noise is to specify an equivalent resistance which, if connected at the grid and if the tube itself were noiseless, would produce the same noise output due to the room-temperature thermal noise in the resistance. This is

[1] Schottky, W., Spontaneous Current Fluctuations in Various Conductors, *Ann. Physik*, **57**, 541, Dec. 20, 1918.
Fig. 4. Thermal noise for various resistances and band widths.

more convenient than a voltage statement because the resistance value does not depend on band width while the voltage value does.

The noisiest tube condition is with temperature saturation, *i.e.*, no space charge. In this case all electrons emitted are immediately drawn to the plate. A diode operated in this way is, in fact, the best standard source of noise for use in measuring the noise figure of a receiver. The presence of the space charge, which makes amplification possible, greatly reduces the tube noise, which is a very fortunate effect.

Values of equivalent grid resistance expressing the noisiness of various tubes have magnitudes[1] generally lying in the ranges given in Table 6.

Mixer noise increases beyond these values if the oscillator injection is insufficient. For amplifiers the effective input noise increases, but the output noise decreases as the gain is reduced by the application of more negative grid bias.

Table 6. Equivalent Grid Resistance Representing Tube Noise for Various Tube Types and Circuits

Tube and circuit	Ohms	Tube and circuit	Ohms
Triode amplifiers	200-2,300	Gradual-cutoff pentode amplifiers	2,400- 14,000
Triode mixers	900-6,000	Pentode mixers	2,800- 35,000
Sharp-cutoff pentode amplifiers	700-7,000	Hexode and heptode mixers	190,000-300,000

Tube noise is an important matter in the early tubes of receivers for the v-h-f and higher-frequency bands. Developmental triodes have been constructed with noise factors as low as 7.8 db at 500 Mc, and 9.7 db at 870 Mc.[2] For tubes operating at much higher frequencies, theory is deficient for the region of the potential minimum and from here to the cathode, but there have been useful advances in the understanding of traveling-wave tubes and the construction of low-noise models.[3]

29. Means for Obtaining Reception despite Noise. There are numerous methods for improving the operation of systems and receivers exposed to electrical noise.[4] Among these are the following:

1. Use as much antenna directivity as possible.
2. Endeavor to have a large enough antenna to intercept sufficient signal to predominate over noise sources in the receiver.
3. Reduce the band width of the receiver as much as the signal characteristics permit.
4. Have as high voltage gain as possible in the coupling between the antenna and the first tube. For this purpose select as the first tube one with as high input resistance as possible.
5. Use an r-f stage to avoid the large noise of mixers early in the circuit.
6. Consider the use of triodes rather than pentodes. In the v-h-f and higher bands consider the grounded-grid triode. At u-h-f and higher bands consider crystal rather than tube mixers.
7. Select particular types of tubes for low noise, especially for the first one or two sockets of the receiver.
8. Use preemphasis in transmission and deemphasis in reception of low-energy portions of band of modulation frequencies.
9. Use volume compression in transmission and volume expansion in reception.
10. Use f.m. or pulse modulation rather than a.m.
11. Consider the use of a squelch circuit. If impulse noise is encountered, consider noise limiters. Squelch- and noise-limiting circuits are discussed in Secs. 93 and 94.

30. External Cross Modulation. A form of interference to which all types of receivers are subject can exist where two or more stations lay down very strong signals in a given area. The trouble arises from poor contacts between various extended conductors in the vicinity, such contacts acting as frequency converters and thereby producing new r-f signals which reach nearby receivers either conductively or by radiation.

S., Principles of Noise Reduction in Communication Channels, *Communication and Electronics* (AIEE), No. 23, p. 44, March, 1956. Lebenbaum, M. T., Design Factors in Low-noise Figure Input Circuits, *Proc. IRE*, **38**, 75, January, 1950.

For example, in Seattle about 1938, three stations on 920, 970, and 1,270 kc each produced strong signals in a large residential area. All three stations together were heard at 620 kc (which is 920 + 970 − 1270) as well as at 1,220 kc (920 + 1270 − 970) and at 1,320 kc (970 + 1270 − 920). At three additional frequencies, two of the three stations were heard; *e.g.*, the 920 and 970 stations were heard at 870 kc (2 × 920 − 970).

An investigation by RMA led to the suggestion that a limitation in the field strengths of overlapping coverages is advisable. A quantity called the "field product" was defined and a maximum of 0.001 recommended for it. (Values of 0.0015 to 0.005 were found in the Seattle cases where trouble existed.) Where three stations are involved, the field product is $\frac{3}{2}F_1F_2F_3$, where the Fs represent the field strengths of the three stations in volts per meter. If only two stations are involved, there are two field products, namely $\frac{3}{4}F_1^2F_2$ and $\frac{3}{4}F_1F_2^2$, and the same maximum of 0.001 applies to these.

Conductors which may form contacts and give rise to external cross modulation include house electric wiring, BX-cable sheath, antenna and ground wires, water pipes, metal lath, gas pipe, and rain spouts. The remedy is to bond the conductors together or separate them with good insulation. Whenever external cross modulation is suspected, the antenna and ground circuits of the receiver should first be checked, and then a filter tried where the power plug is inserted in the receptacle. If necessary, a new antenna with shielded leadin can be tried, and it may be helpful to install a balanced antenna input circuit.

Accounts of theory and practical observations of external cross modulation have been published.[1]

LOOP ANTENNAS IN BROADCAST RECEIVERS

The convenience of the loop antenna, in comparison with outdoor or indoor open antennas, has brought it into general use for standard-band broadcast reception. The directional properties of the loop may occasionally require the user to make a slight rotation of the entire set, since the loop is usually rigidly mounted. This has not been found objectionable.

Medium-size and large cabinets can accommodate an air-core flat loop placed an inch or more from the chassis so as to have an adequate value of Q. However, at about equal cost a ferrite rod with a compact winding can be provided, with the advantage of being suitable for placing near the chassis and in the smallest cabinets. The ferrite type is therefore used in almost all new designs of broadcast receivers for home reception.

31. Voltage Induced in Loop by Wave. The passage of a wave in the direction toward which a loop is turned induces in the loop a voltage given by the formula

$$E = 0.021\mu eNAf$$

where E = induced voltage, μv
μ = effective relative permeability (ratio of flux in coil with magnetic core to value without core)
e = field strength, μv per m
N = number of turns in loop
A = area of loop, sq m
f = frequency, Mc

The ratio E/e is by definition the series voltage in the loop divided by the field strength and is often called the "effective height" from its similarity to the effective height of an open antenna. The formula for the effective height of a loop antenna is, therefore,

$$\text{Eff. height} = \frac{E}{e} = 0.021\mu NAf$$

[1] Ebel, A. J., A Note on the Sources of Spurious Radiations in the Field of Two Strong Signals, *Proc. IRE*, February, 1942, p. 81. Eastman, A. V., and Lawrence C. F. Horle, The Generation of Spurious Signals by Nonlinearity of the Transmission Path, *Proc. IRE*, October, 1940, p. 438. Foster, Dudley E., A New Form of Interference—External Cross Modulation, *RCA Rev.*, April, 1937, p. 18.

where the effective height is in meters and the other quantities are the same as in the preceding paragraph.

The effective heights of loop antennas are small in comparison with open antennas, typical loop values for 1 Mc lying in the range from 0.003 to 0.03 m.

32. Figure of Merit of Loop. The important action performed by a loop and the coupling elements, if any, between it and the first tube is to deliver voltage to the grid of this tube. The ratio of this voltage to the field strength is usually called the "figure of merit," but is also known as the "effectiveness" and the "pickup factor." This is the best single quantity for indicating the performance of a loop and includes the effect of coupling elements, if any, such as a loading coil or transformer. In terms of Q the figure of merit is the product of Q and the effective height; therefore,

$$\text{Figure of merit} = 0.021\mu NAfQ$$

The value of the Q of an air-core loop depends greatly on whether substantial losses are introduced by close location of the loop to the metal chassis. Typical effective values of Q for air-core loops, with coupling circuits if any, lie in the range from 40 to 200.

Typical values of the figure of merit, being the product of effective height and Q, range from 0.12 to 6, which is -18 to $+16$ db. This range applies for air-core loops; ferrite-core loops are often used in quite small receivers for which performance in the lower portion of this range is satisfactory.

33. Air-core Loops. In the case of an air-core loop the designer has the option of using either a high-impedance or a low-impedance loop.

In the high-impedance design the inductance of the loop antenna constitutes all the inductive element of the first tuned circuit of the receiver. This is tuned over the broadcast band by the first section of the gang tuning capacitor. The input connections of the first tube are taken also in parallel to the loop and variable capacitor. This circuit has the advantages of simplicity and a small number of parts.

With this simple circuit the Q of the loop (reduced slightly to represent any other circuit losses) determines the selectivity of the coupling system according to the following formulas:

$$W_3 = \frac{f}{Q} \qquad W_{10} = \frac{3f}{Q}$$

$$W_6 = \frac{\sqrt{3}f}{Q} \qquad W_{20} = \frac{10f}{Q}$$

where W_6, for example, is the band width between the points at which the curve is 6 db down. Any frequency units can be used but must be the same for W and f.

In some designs it will be desired to provide the high-impedance air-core loop antenna with some means whereby an outside antenna can be connected to increase the sensitivity of the receiver for use in regions of low signal strengths.

The most common practice is to connect the antenna to one or two turns of wire around the loop, or the electrical equivalent in the form of an autotransformer obtained by tapping the loop at one or two turns from the low-potential end. However, this type of coupling has the limitation that the voltage gain varies considerably over the band. In a typical case the voltage gain was 9 db (2.8 times) at 550 kc, 21 db (11.5 times) at 1,000 kc, and 24 db (16 times) at 1,500 kc. Such gain in the middle- and upper-frequency parts of the band gives poor image rejection and may cause cross modulation, objectionable tweets, and distortion. In the particular case the coupling system had an image rejection of about 34 db at the l-f end of the band and about 27 db at the h-f end.

One simple step to improve the performance is to insert a resistance of about 500 ohms directly in the antenna connection. One such circuit had a voltage gain of 12 db (four times) at 1,000 kc.

A more thorough remedy is to use a high-inductance primary, so as to resonate the primary circuit below the broadcast band. Windings of 30 to 55 ohms d-c resistance shunted with 50 to 300 $\mu\mu f$ have been used for this purpose.

An economical and effective solution is to retain the low-inductance primary of one or two turns around the loop and add a loading coil and a damping resistor. A suitable circuit is shown in Fig. 5. The coil can be a low-cost solid-wire type. This circuit gives primary resonance either in or near the l-f end of the band, the particular point not being important because the damping by the resistor removes any difficulties in the unicontrol alignment with other tuning circuits. The performance given in Table 7 was obtained with this circuit when using the standard IRE dummy antenna.

Fig. 5. Coupling for use of outside antenna with high-impedance loop.

The i-f rejection in this design can be improved at the expense of the image rejection, if desired, by reducing the 275-μh inductance of the loading coil.

In the low-impedance design of an air-core loop, only a few turns are provided in the loop (these made as large as possible and spaced as well as possible from the chassis) and the remaining inductance of the first circuit is obtained by means of a high-Q series coil. The two may be tuned by the first section of the gang capacitor, or the receiver may be designed for permeability tuning, in which case the inductance of the high-Q series coil can be varied and the capacitance of the first circuit can be obtained from a stable fixed capacitor.

Table 7. Performance of Antenna Coupling of Fig. 5

Frequency, kc	Voltage gain, μ	Db	I-f rejection (455 kc), db	Image rejection, db
550	4.0	12.1	28	59
600	4.2	12.5	32	60
800	4.2	12.5	..	55
1,000	3.8	11.6	36	53
1,200	3.1	9.8	..	50
1,400	2.6	8.3	33	50
1,500	2.2	6.9	..	47

34. Ferrite-core Loop Antennas. The ferrites are crystals having the general chemical formula $M_n(Fe_2O_4)$, where M_n represents any divalent metal or mixture of such metals. Frequently used are nickel-zinc and manganese-zinc.[1] The magnetic properties vary from hard to soft, depending on the materials used, the completeness of crystallization, and the crystal size. In physical character the ferrites are hard and brittle, similar to ceramics, and require some care in handling to avoid breakage.

Early work had shown that powdered pressed ferromagnetic materials used as cores for loop antennas offered certain performance advantages. However, for broadcast receivers the idea was not practical until the availability of the ferrites with their higher permeability and lower loss.[2] The increased permeability is of special value because it attracts a greater flux through the loop so that a small loop area is sufficient to afford adequate signal voltage. Typical core dimensions are ⅜ in.

[1] Gorter, E. W., Some Properties of Ferrites in Connection with Their Chemistry, *Proc. IRE*, **43**, 1945, December, 1955.

[2] Grimmet, C. A., Ferrite Cored Antennae, *Convention Record of IRE*, **2**, Part 7, p. 3, 1954.

diameter and 7 in. length, and the loop has a diameter only very slightly larger with enough turns (*e.g.*, 50) to give an inductance in the region of 150 to 300 μh. The value of Q is held to below 150 or 200 to avoid critical tracking between the antenna and oscillator circuits.

The figures of merit of five ferrite loops measured recently at 1 Mc were expressed in decibels and these values averaged, giving a result of −4.9 db. Values at 0.6 Mc were 3 or 4 db poorer, and those at 1.4 Mc were higher than those for 1 Mc by 1 or 2 db. The 6-db band widths were approximately 9 kc at 0.6 Mc, 18 kc at 1 Mc, and 27 kc at 1.4 Mc.

Since a ferrite-core antenna makes very little use of electrostatic pickup, it is ordinarily much less susceptible to interference from man-made electrical disturbances than are air-core loop antennas.

Sensitivity measurements on receivers using ferrite-core loops require a different procedure from the air-core case, and an IRE standard for this purpose has been adopted.[1] Some of the details from this standard have been given above in Sec. 10.

Loop antennas are also used in direction-finding receivers, for which see Secs. 184 to 186.

35. Precautions Necessary with Ferrite-core Loop Antennas. In two respects the design of a receiver with a ferrite loop requires care which is not needed with an air-core design. One of these is to avoid the ferrite being acted on by 60-cycle magnetic fields, which would introduce modulation hum into the signal on account of the nonlinear characteristic of the ferrite. This has been encountered from the power transformer of a-c receivers and also from the clock (operating on 60 cycles) of clock radios.

The other precaution needed with ferrite loops is with respect to temperature. Above a certain temperature, which depends on the grade of ferrite being used, change of inductance will be substantial and detuning of the antenna circuit will lower the sensitivity of the receiver. The remedy is to determine the highest temperature to be encountered and to provide a grade of ferrite which will withstand this temperature.
Fig. 6. Antenna transformer with high-impedance primary.

36. Antenna Couplings for Sets Accommodating Open Antenna Only. The m-f broadcast receiver designed for the weakest signals, such as in remote rural areas, must rely on a good open antenna. An effective height of 4 m, which is typical of outdoor antennas, is many times greater than obtainable with loop antennas. If few or no strong signals are expected, it is not worth while to provide a loop antenna. The design problem then is to provide good voltage gain and selectivity and also good alignment with other tuning circuits, all for any antenna capacitance within a range of 100 to 300 μμf. From a chronological standpoint this problem was solved before loop antennas became common, and the result has been in wide use for a long time. The solution is shown in Fig. 6, where the 2,000-μh primary winding is sufficient to resonate the primary circuit below 550 kc for any value of antenna capacitance. Coupling of about 10 per cent furnishes enough mutual inductance to transfer adequate signal into the secondary circuit. In the absence of any unnecessary damping, it is necessary to avoid having the primary resonant in the band, as the unicontrol alignment would be seriously affected. The relatively flat voltage-gain curve obtained with this type of transformer shows ratios of voltage on the first grid to the voltage introduced in series with the standard dummy antenna of 5.6 to 7.6 times.[2]

[2] Landon, V. D., contribution to Pender and McIlwain, "Electrical Engineers' Handbook: Communication and Electronics," 4th ed., Wiley, 1950; see pp. 7-115 through 7-117.

The antenna-input system shown in Fig. 7 provides considerably greater coupling between the antenna and the first tuned circuit. This system is employed in automobile receivers where the signal intercepted by the antenna is usually quite small. By connecting a small inductance in series with the antenna so that a series-tuned circuit is formed which is resonant at approximately 2,000 kc, this system will provide a voltage gain which varies from 20 db (10 times) at 600 kc to 26 db (20 times) at 1,400 kc.

Fig. 7. Closely coupled antenna input system with common low-side capacitor.

Another antenna input system which is used extensively in automobile receivers, particularly those designed for a specific car and antenna, is to connect the antenna to a tap of approximately 30 to 50 per cent on the coil in the first tuned circuit.

Permeability tuning for the antenna and r-f interstage couplings of automobile sets is now the general rule because of the economical construction, freedom from microphonism, and convenient adaptability to push-button tuning.

TRANSISTORS AND THEIR USE IN RECEIVERS

37. Transistor Characteristics. Transistors are more costly than tubes, but have the advantages of smaller size and reduced power-supply and heat-dissipation requirements. These qualities have made transistors important devices in equipments where compact construction is essential. The small size of the transistor contributes directly to the desired miniaturization, and the reduced power requirements contribute by needing less cooling area and less space for power-supply parts.

Various types of transistors are available, and there is an extensive literature on their construction, properties, and uses.[1] In addition to the treatment in the present section, reference may be made to Chap. 10 of this handbook.
Fig. 8. Diagrammatic representation of point-contact transistor in circuit.

In common with tubes,[2] transistors have the property of producing amplification, but there are numerous points of difference relating to the mode of operation and to the proportioning of the associated circuits for effective operation.

Transistors are made of a material, particularly germanium or silicon, in the semiconductor class, whence they are often called *semiconductor devices*. From the absence of vacuum or gaseous phenomena they are also called *solid-state devices*.

The first type introduced was the point-contact transistor, having three elements as shown in Fig. 8. In this type two metallic contact points, quite close together, press against a base of semiconductor material. A signal current applied to one of the points, called the *emitter*, so affects conditions in the base that a more or less equal current flows in the circuit of the other contact point, called the *collector*.

[2] Fink, D. G., Transistors versus Vacuum Tubes, *Proc. IRE*, **44,** 479, April, 1956.

Since the internal resistance of the collector circuit is much higher than that of the emitter circuit, voltage gain and power gain are produced. It is seen in Fig. 8 that the base element forms a part of both the input and output circuits, so that this type of connection is called *common-base.* (Common-emitter and common-collector connections are also available.) There is a general correspondence of elements between transistors and tubes, with the emitter having a similarity to the cathode, the base to the grid, and the collector to the plate. In this way the common-base transistor connection corresponds to the common-grid, or grounded-grid, tube circuit; in both cases the output signal has the same polarity as the input signal.

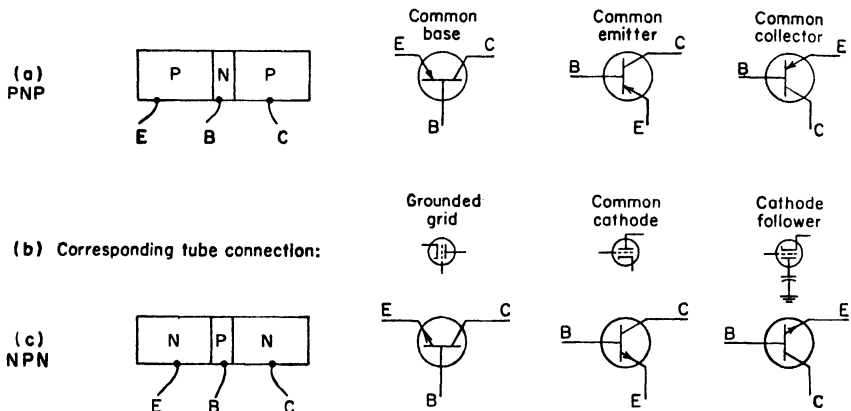
The point-contact type of transistor was announced in 1948 and is still used, *e.g.*, in computers. However, for most purposes the later *junction types* are used, since they


FIG. 9. *P-n-p* and *n-p-n* types of transistors with symbols for their use in the three possible classes of circuits.

have better battery economy and greater power-handling ability, and the interest of the receiver designer will normally be limited to these.

Semiconductors can be prepared to have either a surplus of electrons (in which case the semiconductor is the *n* or negative type) or a deficiency of electrons manifesting itself as "holes" which act like positive charges (in which case the semiconductor is the *p* or positive type). A junction transistor is made by creating in a single crystalline structure a region consisting of a thin layer of either type of semiconductor, acting as a base, between regions of the other type, which act, respectively, as emitter and collector. In this way *p-n-p* and *n-p-n* junction transistors are obtained. These are shown in Fig. 9. Each, like a triode tube, can be used with any one electrode common to the input and output circuits, and the usual representations for these six types of transistor circuits are included in the figure.

The operation of a junction transistor is probably most easily explained[1] in terms of an *n-p-n* type in the common-emitter connection, which comes nearest to resembling tube practice. See Fig. 10. The operation can be considered to consist of the following steps:

1. A junction between *n* and *p* types of the semiconductor operates with rectifier characteristics. This applies to the emitter-base junction and also to the base-collector junction.
2. The base battery places a forward voltage on the emitter-base junction, which causes electrons to travel from the emitter into the base.
3. The signal is added to this base bias, so that the rate at which electrons enter the base region depends on the signal amplitude.

[1] Shockley, W., Transistor Electronics: Imperfections, Unipolar and Analog Transistors, *Proc. IRE*, **40**, 1289, November, 1952. Sparks, M., The Junction Transistor, *Sci. American*, **187**, 28, July, 1952. Kircher, R. J., Properties of Junction Transistors, *Trans. IRE*, **AU-3**, 107, July–August, 1955.

4. The width W of the base is very small, of the order of 0.001 in., so that the electrons entering it mostly pass on into the collector region.

5. The base-collector junction is so biased by the collector and base batteries that electrons entering the collector region are attracted to the output terminal and pass through the load. This is the amplified output. (The base-collector junction has a backward bias in the circuit under consideration because the collector battery always has a greater voltage than the base battery. This polarity serves to collect the electrons entering the collector region.)

6. Power amplification is obtained because the internal resistance of the collector circuit (the output circuit) greatly exceeds that of the input circuit. This permits the matched
FIG. 10. Operation of transistor illustrated by case of n-p-n type in common-emitter circuit.

output resistance to be much larger than the transistor input resistance so that the output signal voltage can exceed the input voltage.

7. The reason for the difference of the input and output internal resistances is that, with respect to the base, the input is biased forward (giving low resistance) while the output is biased backward (giving high resistance).

For a more general explanation of transistor action it is necessary to recognize the existence of majority and minority current carriers. An n type of semiconductor has a surplus of free electrons, and these are the majority carriers for this type of semiconductor. The other type of carrier is the hole, or missing electron, which acts like a positive charge. A few of these are found in an n type of semiconductor and are the minority carriers. In the p type of semiconductor the roles are just reversed, the holes being the majority carriers and the electrons the minority carriers. The existence of the two types of carriers is well established, and measurements of their different mobilities and diffusion constants have been made. Fundamentally, the electron and hole types of carriers correspond to two different types of electron motion.

In terms of majority and minority carriers, the action of either an n-p-n or a p-n-p junction transistor can be summarized as consisting of the following three steps:

1. The emitter junction is biased forward, and the emitter injects its majority carriers into the base. These are minority carriers with respect to the base and are usually referred to in this manner.

2. These injected carriers largely pass on through the base, which is thin, and enter the collector region.

3. The collector is biased backward, giving a comparatively high internal resistance. This bias is opposite to that which would be required for a large original current at the base-collector junction, but is the polarity needed to collect and utilize the carriers entering the collector region from the base. These carriers are minority carriers in the base and are majority carriers in the collector region.

The ratio of collector current to emitter current is slightly less than unity, and is called the alpha (α) of the transistor. This is the signal-current ratio for the common-base connection. For the more frequently used common-emitter connection the corresponding quantity is the ratio of collector to base current, which is $\alpha/(1 - \alpha)$. Present transistors used as audio amplifiers typically afford alphas in the region of 0.97, corresponding to 32 for the common-emitter current gain.

Standard definitions of numerous transistor terms[1] and letter symbols[2] and standard test methods[3] have been adopted by IRE.

The standard letter symbols provide a systematic method of representing the various currents and voltages (average, rms, instantaneous total, instantaneous a-c component, etc.) and also the various impedances, admittances, and operating parameters.

One of the numerous differences between transistors and tubes is that certain transistor characteristics have a considerable dependence on temperature. This manifests itself in greater emitter current and lower collector resistance at higher temperatures, so that further rise of temperature is produced and there is a tendency toward overheating and damage. Stabilization arrangements have been devised,[4] the most widely used being a series emitter resistor.

There has been a steady reduction of the noise of transistors, but they do not yet ordinarily equal tubes in quietness. Recent transistor specifications include types with noise factors (Sec. 19) under 10 db.

At the higher frequencies the value of alpha falls off, and the frequency where it has declined to 70.7 per cent is defined as the *alpha cutoff frequency* and is listed in transistor specifications. Types for audio use typically have values of alpha cutoff in the region of 0.5 to 1 Mc. For subaudio power service this cutoff may be only 20 kc, while for i-f and r-f services and for fast computer use it may be many megacycles.

Progress in the design of transistors for higher frequencies or higher power levels has been steady, and further advances are confidently predicted.[5]

One widely used type of transistor for amplifier service is of the germanium-junction variety made by the *fused-junction* process, also called the *alloying* method. This consists of placing on each side of the base wafer a small amount of a doping agent which under heat will fuse to and alloy into the base material, thus forming the emitter and collector elements. For example, to make a *p-n-p* transistor of this kind, the base wafer is *n*-type germanium and small amounts of indium are placed on each side so as to produce the *p*-type germanium for the emitter and collector.

In distinction to this construction, the *grown-junction* types are formed by slowly pulling a forming crystal from a molten bath and changing the doping of the entire bath at appropriate times so that the emerging crystal has alternating *n* and *p* regions. This process has been extensively used for the production of *n-p-n* transistors.

Increased amplification has been obtained by increasing the emitter injection by the use of aluminum with indium as the *p*-type doping agent for *p-n-p* fused-junction transistors.[6]

Various methods have been used to increase the frequency range of transistors. An important cause of loss for the higher frequencies in junction transistors has been the finite time required for the minority carriers in the base to pass by diffusion from the emitter to the collector. Reduction of the width of the base region (*i.e.*, the distance from the emitter to the collector) has therefore been a primary aim. One method has been drilling a hole into the side of the base wafer to give a reduced dimension and forming the emitter and collector elements at this point.[7] This affords a base width of only 0.0005 in. An electrochemical etching spray is used in another process[8] to produce base widths of only 0.0001 to 0.0002 in. These transistors give

14 db gain per stage as video amplifiers with a 9-Mc band width and give reliable osciliator operation at 70 Mc.

Another technique for obtaining very thin layers is gaseous diffusion in a vacuum oven.[1] This permits thicknesses of less than 1 micron (10^{-6} m = 3.9×10^{-5} in.). Experimental *p-n-p* junction transistors made in this way have had alpha-cutoff frequencies of 500 Mc.

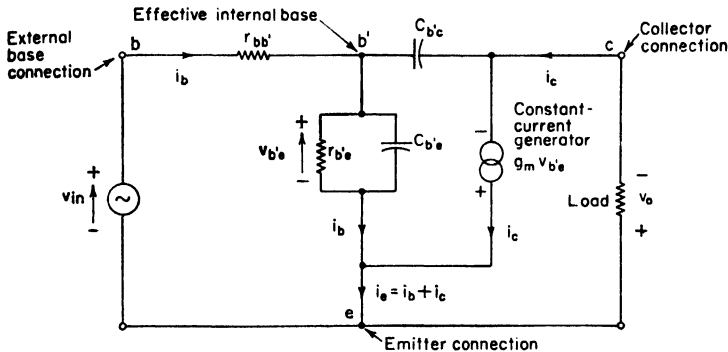
Silicon transistors are more difficult to produce because of the higher melting point of silicon compared with germanium. They have improved characteristics at higher temperatures and good high-frequency performance.[2]


FIG. 11. Equivalent circuit of common-emitter-connected *p-n-p* or *n-p-n* junction transistor applicable over entire frequency range of operation.

An equivalent circuit representing a junction transistor of either the *p-n-p* or *n-p-n* type and applicable over the entire frequency range for which a particular transistor is useful has been devised independently by L. J. Giacoletto of RCA[3] and by C. R. Wilhelmsen of the Hazeltine staff.[4] This equivalent circuit is shown in Fig. 11 and exhibits a similarity to a pentode-tube circuit in that a voltage related to the input signal voltage actuates a constant-current generator in the output connections.

Resistance $r_{bb'}$ is the ordinary (or "ohmic") resistance of the base region between the external base connection and the effective internal base-emitter junction. Resistance $r_{b'e}$ is related to the forward-biased base-emitter junction, and capacitance $C_{b'e}$ is related to the diffusion or transit time of current carriers passing from the emitter through the base to the collector. The transconductance g_m is the ratio of collector-current increment to base-emitter voltage increment. Capacitance $C_{b'c}$ is the capacitance existing at the base-collector junction.

The value of $r_{b'e}$ in Fig. 11 is $KT/[qI_{dc}(1 - \alpha_0)]$, where K is the Boltzmann constant, T is the absolute temperature, q is the charge of an electron, I_{dc} is the emitter direct current, and α_0 is the low-frequency value of the collector-emitter current ratio. Substituting the known constants[5] and assuming room temperature, and also assuming that $\alpha_0 = 0.95$ and that the emitter current is 0.001 amp, it is found that $r_{b'e}$ has a value of 520 ohms. The diffusion capacitance $C_{b'e}$ is approximately $I_{dc}T_dq/(KT)$, where T_d is the average diffusion time of the current carriers in passing through the base region. For audio transistors T_d

$$q = 1.60 \times 10^{-19}$$

may be ¼ μsec, giving a value of 0.01 μf for $C_{b'e}$. For higher-frequency transistors T_d may be only one-tenth as much, giving 0.001 μf. The transconductance g_m is $qI_{dc}\alpha_0/(KT)$, which for the same conditions is 37,000 μmhos. The feedback capacitance $C_{b'c}$ is dependent on the d-c voltage between collector and base, being MV_{CB}^{-n}, where M is a constant of proportionality and the exponent n is about one-half for alloy types and about one-third for grown-junction types. The value of $C_{b'c}$ is approximately equal to the published value of "collector capacitance." Typical values of the various elements of the equivalent circuit for representing two 1955 transistors are given in Table 8. One of these is a grown-junction *n-p-n* type offered for 455-kc service and the other is an alloy-junction *p-n-p* type offered for audio service.

38. Use of Transistors in Receivers. For audio amplification in receivers, as well as in other equipment,[1] transistors offer advantages, especially for compact designs such as for portable use. Transistor audio amplifiers are most frequently connected common-emitter because this connection affords the largest power gain. As a numerical example, the 2N190 transistor with a 9-volt battery in class A operation into a 12,000-ohm load will give a gain of 40 db (*i.e.*, a power ratio of 10,000) and deliver a maximum undistorted output of 0.002 watt. As a class B example, two 2N109s with a 9-volt battery and an 800-ohm load will deliver a maximum undistorted output of 0.2 watt at a gain of 29 db.

For low distortion the addition of negative feedback to the common-emitter circuit may be needed. Another means of obtaining high-fidelity operation is the use of the common-collector circuit, and good results have been reported with a 10-watt design of this kind using two 2N176s in push-pull in the driver and also in the output stage.[2]

Transistor audio circuits can often be designed with few or no transformers. If used, miniaturized designs are generally needed to avoid objectionable size and weight.[3]

Noise originating in transistors departs from the well-known random or "white" fluctuation noise (described in Sec. 27) in the direction of greater noise at lower frequencies; in fact, transistor noise power is inversely proportional to the frequency. Despite this fact, it is possible to obtain satisfactory operation of transistor audio amplifiers with respect to noise by reasonable care in the choice of the type of transistor according to noise-factor ratings and the requirements of the particular application. Types rated below 10 db are available, although as of 1957 most types were higher.

Noise factors as low as 2 db have been obtained in experimental *p-n-p* alloy-junction transistors,[1] and steady improvement in commercial types is to be expected.

The existence of both the *p-n-p* and the *n-p-n* types of transistors permits the cooperative use of the two types in circuit in a manner which is not possible with tubes. This is called *complementary symmetry.*[2] If complementary transistor types can be obtained which have equal corresponding characteristics within the necessary close tolerances, this circuit arrangement has the advantage that a push-pull stage can be designed without transformers and without any input phase inversion. In principle, complementary symmetry can also be applied to a two-stage amplifier with a single transistor in each stage.

For 455-kc i-f service, transistors with an alpha cutoff of 5 Mc or higher will typically afford power gains of 30 db or more per stage. The common-emitter connection is normally used with coupling circuits to match the transistor input, which for this connection is 300 to 1,000 ohms, and also match the transistor output of 20,000 to 100,000 ohms.[3] These types of transistors have collector feedback capacitances ($C_{b'c}$ in Fig. 11) of 5 to 15 $\mu\mu$f and base resistances ($r_{bb'}$) of 75 to a few hundred ohms.

Transformers and other coupling networks for transistors are quite different from those in tube practice because of the different impedance levels. The difference of impedance is especially important on the input side, *i.e.*, at the base-to-emitter input terminals. Suitable design procedures for these coupling systems are available in the literature.[4]

The substantial value of the collector feedback capacitance makes necessary the consideration of neutralization for operation at 455 kc and above. Whether or not to provide neutralization for a 455-kc amplifier is one of the questions to be answered in the design. With common-emitter operation partial neutralization is easily obtained by the addition of neutralizing capacitors from base to base of adjoining stages. More refined methods, sometimes called *unilateralization,* afford virtually complete removal of feedback.[5]

Automatic gain control can be applied to transistors by utilizing the dependence of the gain on either the emitter d.c. or the collector d-c voltage. Decrease of either of these quantities reduces the gain.[6] The addition of a biased diode as another means of control at high input levels may also be advisable.

The small amounts of d-c power required for transistor operation have led to suggestions of equipment utilizing only "free" power, such as solar energy,[7] the acoustic energy of the voice, rectification of waves received from nearby strong radio stations,

the operation of a small hand lever, etc.[1] Silicon transistors are of special interest in this connection.[2]

An all-tube vehicular receiver for military service, operating over the range from 0.5 to 32 Mc, was advantageously redesigned by introducing transistors for all circuit functions except in the front end. The transistorized circuits included the 455-kc i-f amplifier with choice of three band widths, a.v.c., squelch, noise limiter, beat-frequency oscillator for c-w telegraph reception, and a frequency calibrator.[3]

An analysis of transistorization in air-borne equipment revealed a 20 per cent saving in weight, 25 per cent saving in physical volume, and improved reliability of operation.[4]

Broadcast receivers employing transistors,[5] with all power supplied from one or more batteries, can be designed in a variety of sizes, depending chiefly on the required performance and battery life and on the size of a satisfactory miniature loud-speaker.

For medium sizes, such as with 9 in. as the maximum dimension and 4 lb as typical weight, the circuit can include six or seven transistors and a crystal-diode detector, the transistors serving as converter (with or without separate oscillator), two-stage i-f amplifier, first audio stage, and push-pull second audio stage.[6] A paper presented in 1955 by J. L. Nygaard of the Texas Instrument staff reported that a sensitivity of 80 db below 1 volt per m for 0.05 watt output is obtainable in a design totaling six transistors and two diodes and having the following features: (1) a ferrite antenna core of 0.35 in. diameter and 8 in. length; (2) transistor converter; (3) two 2N146 transistors as neutralized i-f stages; (4) crystal-diode detector; (5) transistor first audio stage; (6) two transistors as push-pull second audio stage; (7) crystal antioverload diode connected between ground and a tap 33 per cent up on the antenna winding; and (8) a 9-volt battery. With the antenna-circuit diode and a-g-c bias applied on only the first i-f stage, an a-g-c figure of merit of approximately 60 db was obtained. In general, the performance is similar to that of the conventional four-tube-plus-rectifier receiver in which the four tubes serve as (1) converter; (2) i-f amplifier; (3) detector, a.v.c., and first audio stage; and (4) output audio stage.

For a smaller design, such as with a maximum dimension of 5 or 6 in. and weight of 1 lb, the design can incorporate five to seven transistors and may also include a crystal-diode detector. Two of the transistors serve as i-f stages and one as audio stage. This may be the only audio amplification, or a push-pull output stage may also be provided. A single-transistor converter may be included or separate oscillator and mixer. The performance will vary widely depending on the number of stages. The i-f stages can often advantageously be neutralized, and a.v.c. is normally applied to the first one. Typical battery life is 100 hr.[7]

Broadcast-band receivers for automobiles with 12-volt batteries can be designed with a power transistor as the output stage and with tubes, specially offered for 12-volt plate supply, in the other stages. In this way vibrator, power transformer, and rectifier are eliminated. Transistors offered for such service include the 2N155, 2N176, 2N178, 2M242, 2N257, and the 2N268; these furnish substantial outputs, such as 2.5 watts with 5 per cent total harmonic distortion, as required for automobile service. Data on tubes rated at 12 volts plate supply are given with further treatment of automobile receivers in Sec. 153 of this chapter.

Subject to the availability of suitable types of transistors, automobile receivers can be designed on an all-transistor basis. Compared with an all-tube receiver, this affords a 90 per cent saving in operating power and a substantial reduction in receiver size. An experimental design of this kind[8] with r-f stage, mixer, separate oscillator, two 455-kc i-f

stages, transistor detector, single first audio, and push-pull second audio totaled nine transistors. This design had a performance comparable with conventional all-tube receivers, including a sensitivity (measured at 1 watt output) of 114 db below 1 volt, an a-v-c figure of merit of 63 db, and an undistorted power output of 2 watts.

Transistors are a major element in the miniaturization of receiving equipment, which is discussed in Sec. 130.

R-F AMPLIFIERS[1]

39. Inclusion or Omission of R-f Amplifier. The majority of home broadcast receivers now in use are two-gang a-c-d-c superheterodynes with four tubes and power rectifier, as this design has been found the most popular combination of low price and acceptable performance. A set of this kind has no r-f stage, the four tubes being (1) the converter, (2) the i-f stage, (3) the diode detector and first audio stage in one envelope, and (4) the output stage. The sections of the two-gang variable capacitor tune the antenna coupling and the oscillator section of the converter.

Important advantages afforded by the use of an r-f amplifier with three-gang tuning include prevention of radiation of the oscillator output, reduction of the effect of the high tube noise of the converter, and a large improvement in the rejection of interference at the image and intermediate frequencies.

In special-purpose receivers, such as used in amateur, police, and point-to-point services, one or two tuned radio stages are generally provided. For frequencies up to somewhat in the v-h-f band (*i.e.*, above 30 Mc), pentodes are suitable for this service, especially the 6AK5, 6CB6, and 6DC6. However, at higher frequencies a point is reached where the tube noise of the pentode is objectionable and other methods are necessary to obtain sufficiently low noise factor.[2] Triodes with grounded-grid operation are suitable, especially if preceded by a grounded-cathode triode in the widely used *cascode* circuit.[3] Tubes offered for such use include the 6BQ7A, 6BZ7, and 6AJ4. For still higher frequencies the traveling-wave tube holds promise of affording low-noise amplification. For further treatment of receivers operating above 30 Mc see the text beginning at Sec. 154 below.

An untuned r-f stage used occasionally in medium-sized chassis for home receivers affords the advantages of suppressing oscillator radiation and giving some gain, at the cost of one tube and a very few inexpensive additional parts. Resistance coupling is generally used in such stages, giving a stage gain of 10 to 13 db (3.2 to 4.4 times voltage gain) in the m-f band. If h-f international broadcasts are to be received, a high-transconductance tube must be used in the r-f stage to obtain appreciable gain, and it may be advisable to insert a series coil to resonate with the capacitances of the two tubes at a frequency near the upper limit of the range to be received. For example, a coupling to go up to 16 Mc and work between 10-$\mu\mu$f tube capacitances may include a coil to resonate at this frequency with the 5-$\mu\mu$f series equivalent of the two capacitances. This requires an inductance of 40 μh. A coil of medium quality is sufficient because high Q will give too sharp a peak at the higher frequencies of the desired tuning range.

A series trap for rejection of i.f. may be considered as an improvement for an untuned stage. This has the additional advantage of markedly improving the stability, *i.e.*, freedom from regeneration and tendency to oscillate, of the i-f amplifier of the receiver. Typical trap constants for 455 kc are in the neighborhood of 1,000 μh and 125 $\mu\mu$f, or 2,000 μh and 62 $\mu\mu$f. Factory adjustment and provision for field adjustment are needed. A high Q for this coil is desirable.

40. Inductive Tuning. Automobile broadcast receivers very often employ inductive tuning of the type in which a movable core of compressed powdered iron is inserted varying distances into the coil form to give the required inductance. Such cores are

[3] Wallman, H., A. B. MacNee, and C. P. Gadsden, A Low-noise Amplifier, *Proc. IRE*, **36**, 700, June, 1948.

called "slugs." A typical interstage coupling of this kind has an almost constant Q with a value of about 80 over the band. The inductance range must be about 10 to 1 to cover the range 1,600 to 550 kc. A typical inductance range is 30 to 300 μh resonating with a fixed capacitor of about 250 μμf.

41. Unicontrol Tracking.[1] The superheterodyne with an r-f stage normally requires the alignment of three tuned circuits of quite different characteristics. The r-f interstage coupling is taken as reference, in comparison with which the antenna coupling must accommodate a fixed loop antenna or an open antenna usually having any capacitance within a wide range. The oscillator circuit must, of course, operate at a frequency lying above or below the signal frequency by an interval equal to the i.f. Procedures for proportioning the oscillator circuit are given in Secs. 58 to 60 of the present chapter. For push-button tuning refer to Sec. 61 *et seq.*

In the m-f broadcast band the usual tuning reactors for an r-f stage with capacitive tuning are a coil of about 200 μh and a variable capacitor with a maximum of about 420 μμf. With inductive tuning, typical values are a fixed capacitor of about 250 μμf and a moving-core coil with inductance range from 30 to 300 μh. The capacitors in inductive tuning are normally not actually fixed but are adjustable for alignment purposes.

42. Cross Modulation in R-f Tubes. When a receiver is tuned to a strong signal and there is also present another strong signal of not too different frequency, cross modulation or cross talk may occur. During intervals when there is no modulation on the desired carrier, the modulation of the undesired carrier is heard, but if the desired carrier is absent, the undesired program disappears. The difficulty may occur in an r-f stage in either a superheterodyne or a t-r-f receiver. The cause is the operation of the tube with a total input so large that the linear part of its characteristic is exceeded. Under these circumstances, the tube acts as a modulator and produces a variation in the amplitude of the desired signal in accordance with the modulation of the undesired signal; *i.e.*, the tube gives to the desired signal a modulation from the undesired signal, whence the name "cross modulation." Since the interference becomes part of the modulation of the desired carrier, no subsequent operations can remedy the condition. No special frequency relation exists between the desired and undesired carrier frequencies. In this respect the phenomenon differs from external cross modulation (Sec. 30) and from spurious superheterodyne responses (Sec. 47).

To avoid this fault, the gradual-cutoff, or "variable-mu," type of tube has come into use. Such a tube, if preceded by a single tuned circuit, is normally sufficient to prevent difficulty on this account.

Special care to reduce cross modulation is needed in the design of receivers for mobile reception of radiotelephone messages at 50 and 160 Mc. The selectivity measured with the usual one-signal method may be far less than the effective selectivity, which is impaired by the cross modulation and revealed by the two-signal selectivity test.[2]

The degree to which a given tube will produce this interference can be measured by noting the amount of increase of transconductance when the tube is measured at a low level of signal and then at a substantial level.[3] Another method, described in the same reference, is to measure the tube with a low value of signal and then superpose a substantial signal of considerably higher frequency, again noting the increase of transconductance. The greater the increase of transconductance, the more cross modulation the tube will produce.

SUPERHETERODYNE PRINCIPLE

43. Basic Advantages. Practically all receivers now being made are superheterodynes. This applies to the wide range from low-price broadcast receivers to excellent special-purpose designs.

[1] Langford-Smith, F., "Radiotron Designer's Handbook," 4th ed., RCA, Harrison, N.J., 1952; see pp. 1002–1019.

[3] Herold, E. W., Simple Method for Checking R-f Distortion or Cross Modulation of Pentode Amplifier Tubes, *Electronics*, April, 1940, p. 82.

The advantages of the superheterodyne are primarily the advantages of i-f stages in comparison with t-r-f stages. Much greater amplification and selectivity per stage are realized at i.f. (1) because no provisions have to be made in the i-f amplifier for variable tuning for the selection of stations, and (2) especially because the value of the i.f. can be chosen for the best performance. An additional advantage of the superheterodyne is the increase of stability afforded by the use of an additional frequency range; gains that would almost surely cause oscillation in a t-r-f receiver are easily obtained with the superheterodyne.

44. Analysis of Typical Superheterodyne Performance. The results normally obtained with a good grade of superheterodyne broadcast receiver having two i-f stages are shown in Figs. 12 and 13 in terms of total voltage gain and selectivity. The performance of any one stage is shown by the ratios of the ordinates of the proper two curves at the various frequencies. For example, in Fig. 12 the voltage gain in the second i-f stage at 1,000 kc is total gain to the second detector divided by the total gain to the second i-f grid, or 960,000/16,000, which is 60 times or 36 db. In a similar way the selectivity of each stage at any frequency is obtainable from Fig. 13.

Typical over-all performance of broadcast receivers is given in Sec. 23.

FIG. 12. Voltage gain in successive stages of superheterodyne.

45. I.F. Higher than Signal. In a few cases it is desirable to have the i.f. higher than the signal, *i.e.*, to raise the incoming signal in frequency rather than lower it. Such a circuit reduces the wavelength of the received signal and therefore has been called an "infradyne."

An instance is the 500-kc autoalarm set[1] of the Radiomarine Corporation of America where good image rejection is obtained by the use of a 1,100-kc i.f. The oscillator operates at 1,600 kc, and the image is at 2,700 kc. An autoalarm set maintains a watch for the international distress signal at ship and land stations when the operator is off duty or doing other work.

The use of an i.f. above the signal range gives excellent image rejection but is subject to spurious response at subharmonics of the i.f. and in the case of two signals whose sum equals the i.f. In the former case the converter produces a fixed-frequency i.f. which will "beat" with the normal i.f. (whose exact value varies as the tuning dial

[1] Byrnes, I. F., and H. B. Martin, Automatic Alarm, *RCA Rev.*, January, 1937, p. 49.

is adjusted) and thereby produce a whistle, or "tweet." In the second case the two signals also produce a fixed i.f. with similar results.

46. Double Superheterodynes. For special purposes there is often a need for repeating the frequency change an additional time. This is especially the case in the v-h-f range. In a double superheterodyne there are two i.f.'s, the first of which is usually the higher and is chosen to give the required image rejection. The second i.f. is then chosen for best amplification and close-in selectivity considering the band width necessary to handle the signal. The first i.f. is sometimes adjustable as an additional means of station selection. Since a double superheterodyne has two frequency converters and a detector, it is sometimes called a "triple-detection" receiver.

FIG. 13. Increasing selectivity in successive stages of a superheterodyne receiver.

The value of the first i.f. in double superhets usually lies between 1.5 and 50 Mc for services such as single and multiplex phone. (For radar, where a very wide band width is necessary, the single superheterodyne is generally used.) The second i.f. ranges ordinarily from 455 to 5,000 kc.

The disadvantages of the double superhet are (1) the added complexity and (2) the tendency to give numerous and prominent spurious responses. Considerable design and development work are therefore generally required to produce a model with acceptable performance.

One distinct type of double superheterodyne uses the same oscillator frequency for both conversions. As an instance, the model AN/TRC-1 series of f-m radiotelephone equipments[1] for a range of 70 to 100 Mc have a double-superhet receiver with a single oscillator whose frequency can be adjusted from 37.5 to 52.5 Mc. The first i.f. is variable in all single-oscillator double superheterodynes if a tuning range is provided, and in the present instance it may have any value from 32.5 to 47.5 Mc. The second i.f. is fixed at 5 Mc. Assume that a signal of 80 Mc is to be received, for which the oscillator is set at 42.5, the first i.f. is 37.5, and the second i.f. has its constant value of 5 Mc. As another example, for receiving a 100-Mc signal the oscillator is at 52.5 and the first i.f. is 47.5 Mc. If f is the signal frequency to be received and F is the fixed second i.f., then the oscillator frequency f_o and the first i.f. f_1 are as follows:

$$f_o = \frac{(f + F)}{2} \quad \text{and} \quad f_1 = \frac{(f - F)}{2}$$

[1] Marks, W. S., Jr., O. D. Perkins, and W. R. Clark, Radio-relay Communication Systems in the United States Army, *Proc. IRE*, August, 1945, p. 502.

These formulas give oscillator frequencies higher than the first i.f.'s; if oscillator frequencies lower than the first i.f.'s are desired, the formula for f_1 can be used to get the oscillator frequency, and the formula for f_o to get the i.f.

A multiple superheterodyne of special interest was used on Jan. 10, 1946, by Lt. Col. John H. DeWitt, Jr., and four assistants of the Signal Corps to receive the first radar echo from the moon.[1] The achievement took place at the Evans Signal Laboratory, Belmar, N.J. To obtain the very weak echoes of 0.002 to 0.02 μv per m at the antenna, corresponding to 0.01 to 0.1 μvolt delivered to the preamplifier, it was necessary to reduce the effect of noise by greatly restricting the band width and providing a receiver of very low noise figure. The equipment consisted of a much modified SCR-271 radar in which the original operating frequency of 111.5 Mc was retained. A band width of only 57 cycles was used, which was sufficient for the pulse of ¼ sec duration sent out every 4 sec. The trip to and from the moon requires a total of 2.4 sec. To realize the necessary narrow band width, very precise control of frequency was required, and in addition the Doppler change of frequency on reflection at the moon had to be taken into account. This effect amounted to 300 cycles and changed in sign according to whether the observations were being made at moonrise or moonset. The most practicable way of meeting the requirements as to frequency stability and band width with the available equipment was to employ a quadruple superheterodyne, the i.f.'s being approximately 33 Mc, 6.7 Mc, 1.6 Mc, and 180 cycles. The 57-cycle band width was obtained with a pass band of approximately 150 to 210 cycles for the last i-f amplifier centering at 180 cycles. The echo from the moon was seen on a scope and also heard as a pulse of 180-cycle tone every 4 sec.

The antenna had a gain of 23 db over an isotropic radiator. The preamplifier of the receiver was a special design with a noise figure of only 5 db. It had three stages of which the first two were grounded-grid 6J4 triodes, a miniature type with the high transconductance of 12,000 μmhos. The noise power was doubled by the acceptance of the image in the frequency conversion from 1.6 Mc to 180 cycles, so that the noise figure of the entire receiver was 8 db.

47. Spurious Responses in Superheterodynes. The selectivity of a superhet in terms of selectances and of band widths at certain input ratios is not a complete indication of the actual selectivity under all conditions, as this type of receiver is susceptible to certain kinds of interference which are not encountered with a t-r-f receiver.[2] The susceptibility to these interferences is a result of frequency conversion. Considerable care may be necessary to distinguish interference of this general type from that due to cross modulation or external cross modulation.[3]

The discussion in the following paragraphs is primarily for the case where the i.f. is lower than the received frequencies. For spurious responses when the i.f. is above the received frequency range, see Sec. 45.

48. Image Interference. The most important spurious response in a superheterodyne is usually the image. With the set tuned to a particular desired signal, the image lies on the other side of the oscillator, each being separated from the oscillator by the i.f. For example, a receiver tuned to 1,000 kc and having an i.f. of 455 kc is subject to image interference at 1,910 kc. Any receiver with this value of i.f., when tuned to any station, is subject to image interference at a frequency 910 kc higher than the desired station.

Since the function of the converter is to produce the difference between applied frequencies, it cannot distinguish between the signal and the image and produces i-f output from each. The only remedy for image interference is increased general r-f selectivity ahead of the converter, or special circuits[4] designed to have a high attenuation at the image frequency, wherever it may be, as the tuning dial is adjusted to select any desired station. The simplest means for obtaining image rejection is to tap down the output lead on the tuning inductor. This can be done to give theoretically infinite attenuation at one frequency and substantial improvement over a band. The tap

[3] A useful comprehensive table, "Analysis of Radio Interference Phenomena," appeared in *RCA Radio Service News*, February, 1946, and was reprinted in *Radio News*, June, 1946, p. 54.

[4] Wheeler, Harold A., Image Suppression in Superheterodyne Receivers, *Proc. IRE*, June, 1935, p. 569.

an antenna dimension can be expressed in wavelengths by the ratio of the physical length to the wavelength (expressed in same units as length) corresponding to the frequency, or in electrical degrees (or radians) by the product of the dimension in wavelengths and 360 deg (or 2π radians). For example, at a frequency of 10 kc, *i.e.*, 3×10^4 m wavelength, the vertical length of an antenna 300 m high can be expressed as $V = 300 \text{ m} = 0.01\lambda = 3.6 \text{ deg} = 0.0628$ radian.

The lowest frequency at which the antenna system in Fig. 4 is resonant is defined as the fundamental frequency, and the corresponding free-space wavelength is defined as the fundamental wavelength λ_0. The effective (or apparent) electrical length G of this antenna system at the fundamental frequency is $\lambda_0/4$, or 90 electrical degrees. For any vertical length V, the effective length is a function of the length of the top-loading section H and the diameter of the vertical section D.

FIG. 4. Empirical values for the constant K used in determining the wavelength of T antennas.

If the fundamental frequency, and hence wavelength, of this antenna system is known, its effective electrical length G at any other frequency can be obtained from

$$\begin{aligned} G &= \tfrac{1}{4}(\lambda_0/\lambda) && \text{wavelengths} \\ &= 90(\lambda_0/\lambda) && \text{degrees} \\ &= (\pi/2)(\lambda_0/\lambda) && \text{radians} \end{aligned}$$

where λ is the wavelength corresponding to the frequency.

The fundamental wavelength can be obtained from the following approximate relations or from measurements on scale models. For an antenna without top loading, or a vertical tower of uniform cross section, the following formula applies to within approximately 4 per cent.

$$\lambda_0 \doteq 1.33V \qquad \text{m}$$

where V = vertical length (height), ft.

For top-loaded symmetrical T antennas the fundamental wavelength can be predicted only approximately from simple formulas, and for large-area flattop systems it usually must be estimated or measured from scale models. Many empirical factors are the cause of this uncertainty, including the ratio of horizontal to vertical lengths, the capacitance of insulators, the proximity of grounded or insulated towers, the number of conductors used and their cross-sectional configuration, reflections from the T junction, and perhaps other factors. It has been found from practical experience that the following empirical relation for the fundamental wavelength can be used for a symmetrical T antenna.

$$\lambda_0 \doteq K(V + H/2) \qquad \text{m}$$

where the antenna dimensions are in feet, λ_0 in meters, and K is taken from Fig. 4. This figure was derived from 24 actual antennas which were carefully measured. The antennas were of different sizes and with several different tower arrangements. This unusual curve accounts within 5 per cent for all but four of the antennas. The corners in the curve are based on reliable data and so were not rounded out. The value at the right-hand extremity of the curve is based on three identical l-f antennas constructed in three different locations and measured by separate qualified individuals with exact concordance.

In some cases the effective electrical length G of an inverted L or T antenna can be taken as the sum of the vertical and horizontal parts in electrical degrees (or radians) provided that the horizontal distances from the junction with the vertical are electrically small. For capacitance-area loading of empirical form, calculations may be difficult. In such cases, it is desirable to use a scale model (the scale being in size

directly proportional to the wavelength) erected over a metallic plane of area very large with respect to the flattop. The supports should also be modeled and the location of antenna and guy insulators simulated. For reactance measurements, the cross section of the antenna conductors should also be to scale.

9. Radiation Resistance and Field Strength. The radiation resistance can be increased by increasing the vertical length (see Fig. 5) and/or by producing, as nearly

FIG. 5. (*Left*) Radiation resistance for electrically short antennas vs. height of vertical portion (degrees) and (*right*) ratio of currents at top and base of vertical portion.

as possible, a uniform current distribution on the vertical portion of the antenna. The latter is usually done by some capacitance loading at the upper end in the form of an inverted L, a T, or a large flattop in the form of a ring or spider.

The radiation resistance of a loaded antenna can be calculated from the following (see Fig. 5).

$$R_r = \frac{30}{\sin^2 (L + B)} \left[\frac{4L^2}{3} \sin^2 B + \frac{2L^3}{3} \sin 2B + \left(\frac{17}{30} \cos 2B - \frac{7}{30} \right) L^4 \right] \quad \text{ohms}$$

where L = vertical length (height), deg

B = effective lengthening of the antenna due to the top loading, deg; $L + B = G$

When $B = 0$, $R_r = 10L^2$ (L in radians). The above relationships are valid for $L \leqq \lambda/12$ ($L \leqq 30$ deg) and are shown in Fig. 5.

FIG. 14. Chart for identifying whistles heard with superheterodynes having an intermediate frequency of 455 kc.

where m = desired modulation percentage
E_w = output whistle voltage
E_s = signal output for 30 per cent modulation at 400 cycles

As an example, if E_w should equal E_s, the value of m would be 30 per cent, which would be reasonable as indicating equality to the 30 per cent signal modulation.

The test is repeated at representative signal levels. The results give a clear picture of the minimum whistle interference which characterizes the set, since in this test there is no interference to aggravate the situation. In this test, whistles will be found at harmonics of the i.f. and possibly at other points.

A two-signal test is also provided in the IRE Standards which simulates the practical case where the receiver is tuned to a given frequency but subject to interference over a wide frequency range. One of the signal generators supplies the input to which the set is tuned, and the other generator is used to explore for whistles. As each one is located, a measurement is made of the input of the "interfering" signal generator necessary for the whistle, when tuned to 400 cycles, to be 30 db below standard output. The results are plotted as a spectrum with frequencies as abscissas. The ordinates are decibels below 1 volt plotted linearly or microvolts plotted logarithmically.

FREQUENCY CONVERTERS

53. Essential Function. The frequency-changing function is performed by a modulator, or mixer. This requires the r-f signal and also the output of a local oscillator, and delivers an i-f signal. The general theory of modulators is given in Chap. 12. The modulator, or mixer, and the oscillator are generally called a "converter." The mixer and oscillator of a converter may be in either the same or separate tubes. One classification of converters is according to whether the signal and heterodyne inputs are applied at the same electrode or at separate electrodes and, in the latter case, according to whether the electron stream is first influenced by the heterodyne or by the signal voltage. The mixer function can be performed by any element which can be so operated as to have a nonlinear instantaneous input-output characteristic, including tubes of diode, triode, and multielement types, and also crystal diodes and transistors.

54. Converter Performance in M-f Broadcast Band. The most widely used converter tubes for the reception of sound broadcasts are heptode oscillator-modulators, such as the 6BE6 and the 12BE6, having the oscillator function associated with the first grid and the signal input voltage applied on a later grid. These are also called *pentagrid converters.* They afford conversion transconductance (ratio of i-f current to applied r-f signal voltage) of 425 to 550 μmhos with a plate supply of 250 volts. The corresponding battery tube, the 1R5, is rated at 235 to 330 μmhos at plate voltages from 45 to 90 volts. In socket-power operation, "conversion gain" (i-f voltage on first i-f grid divided by r-f signal voltage on converter input grid) of forty to sixty times is normally obtained over the standard m-f broadcast band. A-v-c bias voltage can be applied to the return connection of the r-f signal input grid, and lower conversion gain can thus be obtained for improving the a-v-c figure of merit.[1]

55. Converters for the 100-Mc F-m Band. A frequency converter for the f-m band of 88 to 108 Mc is available in the 6BA7 heptode, which for separate-oscillator service is rated at 900 to 950 μmhos conversion transconductance. It can also be used in a self-oscillating design.

For high-grade performance, such as in tuners for high-fidelity installations, separate triode oscillators are normally provided, often in the same tube envelope with the mixer. Examples of such triode-pentodes are the 6U8 and the 6X8. The 12AT7 double triode affords separate triode sections suitable for oscillator and mixer use. If a.f.c. is to be provided, the mixer can be a separate triode (*e.g.*, 6AB4) or pentode (*e.g.*, 6SH7, 6BC5, or 6AU6), and the oscillator and a-f-c functions can be obtained in a double triode, such as the 12AT7, 6J6, or 6BK7A.

Oscillator frequency drift accompanying warmup of the receiver can be controlled by a.f.c. (per Sec. 96 *et seq.*) or by careful attention to the characteristics of the oscillator tube, the various other circuit parts, and the use of temperature-compensating capacitors.[2]

56. Germanium Crystal Converter for V.H.F. At frequencies in the v-h-f and lower part of the u-h-f range germanium crystals offer the advantages of compactness, absence of heater power requirements, and good electrical characteristics. The characteristics of four representative types are given in Table 9. Numerous other types of germanium diodes having EIA designations are available with substantial ranges of characteristics and in various housings. Frequencies up to 900 Mc are within the ratings of the 1N124A, 1N133, and 1N147, which are offered for mixer service in u-h-f television receivers. The 1N93 and 1N153 are rated to 300 volts instantaneous inverse potential. The 1N56A and 1N71 can handle 0.060 amp average current and have minimum forward current at +1 volt of 0.015 amp.[1]

Table 9. Characteristics of Typical General-purpose Germanium Crystal Diodes

Property	1N34	1N126	1N38	1N127
Max working volts	60	60	100	100
Min forward current at 1 volt, amp	0.0085	0.005	0.0075	0.003
Max reverse current	800 μa at −50 volts	850 μa at −50 volts*	25 μa at −10 volts	25 μa at −10 volts†
Max transient or surge current, amp	0.5	0.35	0.5	0.3
Max continuous d.c., amp	0.04	0.03	0.0225	0.03

* Maximum reverse current at −10 volts is 50 μa.
† Maximum reverse current at −50 volts is 300 μa.

57. Silicon Crystal Converter for U.H.F. and S.H.F. In the range from 1,000 to 55,000 Mc, the fixed silicon crystal with tungsten point is generally used as a converter because of its low noise and moderate conversion loss.[2] Below 2,500 Mc tube converters can be employed with the advantage of greater electrical ruggedness but the drawback of poorer operating performance. Table 10 gives characteristics of various silicon crystals which are available for different frequencies.

Crystals must be protected from electrical overload, such as due to poor duplexer operation in radars. The burnout-test energy in a "spike" of admitted transmitter output is only 0.3 to 2 ergs for 3,000-Mc crystals, 0.3 to 1 erg for 9,000- and 10,000-Mc types, and 0.1 erg for the 25,000-Mc type 1N26. For 1,000-Mc service, the Western Electric 1N25 is available with the high value of 6.5 watts burnout pulse power.

At lower frequencies crystals produce more noise for a given band width.[3] This is true below 1 Mc and especially in the a-f range.

Most types of silicon crystals are designed for operation at or close to a particular radio frequency. In distinction, the 1N286, 1N358, 1N369, and 1N369A have acceptable performance over the entire band from 10 to 22 kMc.[4]

Radar development work has shown that a mixer can produce substantial noise

merely because of the presence of the noise in the applied injection from the local oscillator.[1] A remedy is available in the now conventional use of two mixers so arranged that their desired outputs add but their outputs of noise from the oscillator cancel. The r-f plumbing for this purpose can consist of a magic tee or of a "rat race," either serving to apply the signal and oscillator inputs to one mixer with a given phase relation but to the other mixer with one of the inputs reversed in polarity.[2]

Table 10. Typical Silicon Crystals for U-h-f and Higher-frequency Service

Approx max frequency, Mc	For converter service in superheterodynes				For detector service in "crystal video" receivers	
	Crystal type	Max conversion loss, db	Max noise-power ratio	Impedance as i-f source, ohms	Crystal type	Impedance as video source, ohms
1,000	1N25	8.0	2.5	100-400		
3,000	1N21C	5.5	1.5	200-800	1N32	5,000-20,000
7,000	1N150	6.0	2.0	250-500		
10,000	1N149	5.5	1.5	325-475	1N31	6,000-23,000
16,000	1N78A	7.0	1.5	365-565		
25,000	1N26	8.5	2.5	300-600

55,000	Experimental wafer type	8.5	1.7-2.2*	250-500		

* Average rather than maximum values.

A slight improvement in crystal-mixer operation, with respect to reduction of conversion loss and of noise, may be obtainable by preventing the loss of energy at the image frequency. Such energy can be present as a result of demodulation between the oscillator second harmonic and the r-f signal and also as a result of the new i-f signal modulating the oscillator fundamental.[3]

Fig. 15. Method of varying inductance slightly in factory for tracking purposes.

UNICONTROL STATION TUNING

58. Tracking Requirements. A superheterodyne receiver having an r-f stage involves two problems to achieve single-dial tuning. One, also present with the t-r-f receiver, is the tracking of the antenna coupling circuit to the r-f interstage circuit in such a way as to accommodate the necessary range of antenna capacitances. The use of a high-inductance primary in the antenna transformer for this purpose is described in Sec. 36.

To secure satisfactory alignment, fixed tuning elements such as coils are usually made with very close tolerances. For this reason coils are sometimes wound in two sections, as shown in Fig. 15. With this construction one or more turns in section *a* can be transferred to section *b* so as to increase slightly the total inductance of the

coil. It is evident that this will increase the inductance because in the limit, when all of *a* is transferred to *b*, the coupling between the turns formerly constituting *a* and the remainder of the coil is increased, which increases the total coil inductance. Conversely, if the inductance of the coil is too high, it can be reduced slightly by transferring turns from *b* to *a*. After this factory adjustment a suitable lacquer is applied to hold the turns in place and protect them from humidity. Instead of such close adjustment it is sometimes practical to sort coils in the factory according to their inductance and then use similar ones together; *i.e.*, if the tuning coils of all circuits are slightly high but in corresponding amounts, the single-dial tuning will not be disturbed beyond a slight permissible error in the frequency as indicated on the dial.

The superheterodyne, in addition to antenna tracking, introduces the problem of oscillator tracking, with the requirement that the oscillator circuits differ accurately from the signal circuits by just the amount of the i.f. The oscillator almost always is set at a frequency higher than the signal because this gives a smaller value for the ratio of maximum to minimum oscillator frequency. The smaller value of this ratio is desirable because it permits a much smaller variation of the tuning reactor in the oscillator circuit, which results in a cost saving.[1]

Very large ratios of maximum to minimum frequency in one tuning range in the v-h-f and u-h-f bands, such as 50 to 1,000 Mc, are obtainable by using fixed capacitive electrodes adjacent to suitable movable coils.[2]

59. Tracking with Capacitive Tuning. The simplest method of obtaining oscillator alignment in sets for quantity production is to have a section of the capacitor gang with a smaller number of specially shaped plates so as to produce the required oscillator frequency at all points of the dial. Such a capacitor gang is said to have a "cut-plate" section. In a typical design for an i.f. of 455 kc and covering 540 to 1,630 kc, the signal circuit may consist of a 200-μh coil and a tuning capacitor with a maximum of 420 $\mu\mu$f. The oscillator section consists of an 80-μh coil and a cut-plate section of the tuning gang with a maximum capacitance of 160 $\mu\mu$f. The reduction of oscillator tuning capacitance saves chassis space owing to the shorter length of the capacitor gang and the smaller space required for the emerging rotor of smaller radius. A capacitor gang with a cut-plate section is generally avoided in receivers having more than one tuning band but is frequently found in sets receiving only the standard broadcast band.

Capacitor gangs with identical sections can be used by employing a suitable value of inductance in the oscillator and by employing series and shunt capacitors. A method of computing the proper inductance and proper values for the associated capacitors is given by Roder.[3] This gives a "three-point tracking"; *i.e.*, the alignment is perfect at three points in the band. The choice of inductance, which is a design and factory matter, determines the frequency near the center of the band at which the tracking is perfect. A series capacitor furnishes perfect tracking at a point near the l-f end, and a parallel capacitor near the h-f end. These two capacitors are normally adjustable in the field whenever necessary to restore satisfactory alignment.

A simplified procedure for determining the oscillator inductance and the series and parallel capacitors has been described[4] together with an illustration for coverage of the h-f range from 7 to 15 Mc. Lumping all the minimum circuit capacitance together into a total of 20 $\mu\mu$f and using a capacitor with a maximum of 83 $\mu\mu$f with a signal tuning inductance of 5.6 μh, the oscillator inductance was found to be 5.2 μh, the series capacitor 1,370 $\mu\mu$f, and the parallel capacitor 0.3 $\mu\mu$f.

60. Tracking with Permeability Tuning. In automobile receivers, permeability tuning has largely displaced capacitor tuning. This brings up various questions with regard to the tracking of the oscillator.[1]

There is a limited use of designs in which the variable inductor for the oscillator circuit is identical to the inductors in the signal circuits. In this case, a small series inductor followed by a shunt inductor and by the fixed tuning capacitor can be used to obtain three-point tracking. In a typical example,[2] the tuning inductors had a range from 120 μh at 1,600 kc to 1,000 μh at 550 kc, the signal tuning capacitance being 80 $\mu\mu$f. In the oscillator circuit, the identical inductor was followed by a 26-μh series coil, a 1,127-μh parallel coil, and a 46-$\mu\mu$f fixed tuning capacitor. The i.f. in this design was 455 kc.

Instead of the series and parallel inductors, it is often possible to obtain the effect of the series coil without actually having it present by the expedient of a thicker coil form, and to obtain the effect of the parallel inductor by the use of a tapered winding. This amounts, of course, to employing a different inductance coil in the oscillator circuit. Formulas applicable to this case have been given[3] in the literature.

PUSH-BUTTON TUNING

Tuning by means of push buttons offers freedom from fine tuning. It is an important feature in the design of automobile receivers, and to a less extent with other types of receivers.

61. Mechanical Rotation of Tuning Gang. One available method is to provide an arrangement of mechanical elements by which the user can push a particular button
FIG. 16. Rocker-bar type of mechanical push-button tuner.

with sufficient force and through a sufficient distance to rotate the tuning capacitor to the required position. A stop establishing a limit of travel is provided to serve as an indication to the user that the capacitor is at the required position.

A widely used mechanical method of preset tuning has a semicircular pawl or disk which is advanced by the push button, as shown in Fig. 16, the diameter edge of the pawl moving ahead in the direction of the button travel. This pawl encounters a

[1] Fairman, Harry E., Oscillator Tracking Methods in Permeability Tuning, *Tele-Tech*, March, 1947, p. 48. Wessels, P. S., Design of Slug-tuned Superheterodyne Receivers, *Electronics*, **25**, 176, November, 1952.

[3] DeCola, Rinaldo, A Superheterodyne Tracking Solution, *Electronics*, February, 1942, p. 29.

double-arm rocker bar which controls the position of the tuning gang. One end of the pawl encounters the arm on one side of the rocker bar and pushes it ahead until the other side of the rocker bar strikes the other end of the pawl, thus determining the end of button travel and the final position of the rotor of the tuning gang. In this type of mechanism, the preset station for each button can be changed by (1) releasing the adjustment clamping screw, which leaves the pawl free to rotate about its axis; (2) pressing the particular push button and holding it in; (3) tuning in the desired new station with the manual tuning control of the set; (4) tightening the adjustment clamping screw; and (5) releasing the push button. Capacitors with this preset mechanism are designed to go through their entire capacitance range in 90 deg of rotation, and good ratios of maximum to minimum capacitance are obtainable. If a 180-deg capacitor is to be used, a 2:1 stepup gearing is provided.

Another practical method of mechanical push-button tuning has heart-shaped cams on the shaft of the variable capacitor, one such cam for each preset station. Pressure on the push button brings a small roller against the cam and thus rotates the capacitor shaft until the roller ends its travel in the vee of the heart; here the roller is nearest the shaft and can go no farther, and the shaft has been rotated to the desired position. A clamping arrangement allows the cams to be loosened for resetting the stations assigned to one or more of the push buttons.

62. Mechanical Control of Slug Position. Push-button control of permeability tuners can be obtained by mounting the ends of the slugs on a common bar which then moves them into their respective coils. Another arrangement is to use cords to connect the slugs to the tuning dial in such a way that rotation of the dial pulls on one slug, the back end of which is tied to the next slug, the back end of which is tied in turn to the other side of the tuning dial.

63. Multibutton Self-disengaging Switch. Other types of push-button tuning are electrical in character so that the only function of each push button is to perform certain electrical connecting operations. One requirement on a gang switch of this kind is some type of latching mechanism to hold any button pressed and yet so arranged that pressing any button disengages whatever button was previously pressed. Moderate cost is, of course, necessary for these switches to be used in broadcast receivers, and in some types of circuits low capacitance is also required. The self-disengaging feature is obtainable with a latch bar by which the first effect of pushing any button is to disengage the previous button, after which further travel of the button makes the desired connections. The last button operated ordinarily stays more or less depressed to show the user what station is tuned in.

64. Single-button Switch. An extensive use has been made of a single button as the entire preset tuning control available to the user. This has been found acceptable, especially in automobile receivers. Pressing the button causes the set to change from one preset station to the next preset station in a cyclical manner. The receiver in this case includes a solenoid-operated rotary switch which moves around one position for each operation of the single control button. An indicator, such as a numbered or lettered dial behind a window, indicates at all times what preset station is being received.

A more elaborate single-button design can be made, specially devised for autoists traveling in more than one region, in which a spring-operated or motor-operated sweep is employed to bring in the next available station on the air. Each time the button, or bar, is pressed, the tuner progresses to the next station in order of frequency, automatically returning to the other end of the band whenever necessary. There is no presetting of stations, and the receiver can be said to have a "self-readjusting push-button" feature. Further discussion of this type of operation is given in Sec. 153 below.

65. Station Choice by Preset Reactors. A frequently used electrical type of push-button tuning employs preset reactors for the choice of stations. Ordinarily one such reactor is provided for the tuning of the antenna coupling and one for the tuning of the oscillator. In sets having a tuned interstage coupling for continuous tuning, the r-f stage is usually switched out of the circuit for push-button tuning.

The best combination of stability and low cost appears to be the use of preset capacitors for antenna tuning and preset inductors for oscillator tuning. The function of the switch is to select the necessary pair of reactors to tune in the desired station.

66. Motor-operated Tuners. A limited number of sets with motor-operated tuners have been made in which an electrical motor is provided for rotating the tuning capacitor to the required position. The determination of this position, as shown in Fig. 17, is made by providing a disk, which is essentially a two-bar commutator, and several narrow contact brushes, one for each preset station. A contact resting on one-half the disk will cause the motor to turn in one direction, while if it rests on the other half the motor will turn in the opposite direction. With this arrangement, whenever any button is pushed, the motor starts turning in the proper direction to rotate the capacitor shaft directly toward the desired point. As the capacitor rotates, the commutator moves until the insulation between the two halves of the disk is under the contact point, at which time the desired station is tuned in and the motor stops. The setting up of the chosen stations requires only that each contact be positioned around the disk at the necessary angle.

In practice, the contacts are usually arranged in two concentric guide channels. This permits setting two contacts to stations which may be close together in frequency. For setting the contacts, the desired station is tuned manually and the appropriate contact slid around its guide slot until it is on the insulating strip. A fairly high tuning speed can be provided since, if the momentum should cause the tuning to overshoot, the motor will automatically reverse and return to the correct point, where it will stop.

Fig. 17. Motor-operated preset tuner with control disk to start motor in the proper direction to go toward any desired preset station.

67. Frequency Stability. Stability of the various circuits, which is desirable in any receiver, is important for push-button sets. This matter has been the subject of much study and development, and the art is now in a satisfactory state in the sense that almost any desired precision can be obtained at moderate expense. In addition to components less subject to temperature drift,[1] compensating elements have been developed. Within the receiver the problem has been attacked by the use of a wider top i-f selectivity curve and in some elaborate receivers by the provision of a.f.c.

68. Receiver Silencing. Tuners which move the capacitor or inductor gang from one position to another should be provided with a contact for disabling the receiver during the time the change of tuning is in process. Otherwise a disagreeable series of sounds from the various stations passed through in the tuning will be heard. This does not apply to tuners that operate by making a quick change of preset reactors. A

[1] Mistic, G., Temperature Compensating Capacitors, *Elec. Manufacturing*, **57** (2), 83, February, 1956. Sturley, K. R., "Radio Receiver Design," Part I, 2d ed., Wiley, 1953; see pp. 390–404.

ground on the grid of an audio stage can be used to quiet the receiver where necessary during the change of tuning, the arrangement being such that silencing is accomplished in an automatic and economical manner.

69. Remote Control. Some push-button tuning systems lend themselves to convenient employment for remote control, if choice among preset stations, without continuous tuning, is sufficient. The single-button tuner is an outstanding case of this kind since only two wires are required for the tuning. Motor-operated types can also be used for remote control but require a multiconductor cable. Further treatment of remote control is given in Sec. 105.

70. Preset Tuning at Higher Frequencies. Various preset tuners have been devised for aviation, maritime, and military equipment operating at frequencies above the standard broadcast band. In Western Electric equipment, a telephone dial is used to tune quickly to one of as many as 8 or 10 preset frequencies. Another tuner, the Collins "Autotune," has been used extensively in military equipment. This is a motor-operated type which has for each preset frequency a circular disk with a gap into which a detent pawl enters, thus stopping the rotation of the shaft at the required point. It makes a change from one preset tuning to another in 5 sec or less.

I-F AMPLIFIERS

Numerous factors must be considered[1] in the design of the i-f amplifier, particularly in equipment for special services. These factors include the choice of the intermediate frequency, number of stages, gain and selectivity required, whether variable selectivity is to be provided, whether stagger tuning is necessary, etc.

71. Choice of I.F. The chief considerations are (1) better image rejection is obtained with higher values and (2) better gain and selectivity in the i-f amplifier are obtained with low values. With broadcast receivers, the most widely used i.f. is 455 kc; for automobile receivers either 455 or 262 kc is used. For the f-m broadcast band (88 to 108 Mc) the i.f. of 10.7 Mc is generally used. In television receivers the value of the picture carrier in the intermediate stages is either about 46 or about 26 Mc. Radar receivers, with carrier frequencies in the u-h-f and s-h-f ranges, usually employ i-f amplifiers operating at 30 or at 60 Mc. A limited use has been made of i.f.s above 100 Mc.

One of the considerations bearing on the choice of i.f., especially for fixed-frequency operation such as in the point-to-point services, is to avoid values that might cause spurious responses due to high-order frequency conversions in the mixer tube.[2]

72. Typical I-f Amplifier Performance. A single i-f stage is usually sufficient in broadcast receivers, especially if only the standard broadcast band is to be accommodated. Such a stage is usually provided with input and output tuned transformers, each having tuned primary and secondary windings, the coupling being about 1 per cent and the Q about 90, so that the coupling is slightly under optimum, with the advantage that manufacturing tolerances do not result in any of the product having a double-peaked characteristic. The i-f gain of such a stage is ordinarily around 40 db, the band widths about 16 kc at 6 db and 44 at 20 db. The inductance of each winding is generally about 1.0 or 1.1 mh, requiring a capacitance of about 120 $\mu\mu$f.

Sets accommodating the f-m broadcast band usually have 10.7-Mc i.f. and two intermediate stages. The first 10.7-Mc i-f stage usually has a gain of about 29 db and band widths of 240 kc at 6 db and 600 kc at 20 db. The second stage has a gain of about 26 db with greater band widths, representative values being 460 kc at 6 db and 2,100 kc at 20 db. Composite i-f transformers can be used, in which one metal can houses both the 455-kc and the 10.7-Mc elements.

Amplifier, *Proc. IRE*, **36**, 474, April, 1948. Adams, J. J., Intermediate-frequency Amplifiers for Frequency-modulation Receivers, *Proc. IRE*, **35**, 960, September, 1947.

[2] Charts for assisting in this evaluation have been prepared by R. S. Badessa, Mixer Frequency Charts, *Electronics*, August, 1946, p. 138.

73. Choice of Inductance. To obtain maximum gain in an i-f stage, the L/C ratio should be as large as possible with stability. Too high a value, obtained with small values of C, however, makes the variations of the input capacitance of the following tube produce excessive misalignment of the tuning circuit. For this reason values of C are seldom below 30 or 40 $\mu\mu$f, corresponding at 455 kc to 4 and 3 mh. Battery receivers, which must have high gain with limited plate voltage, use inductances between 2 and 3 mh.

With sets having two i-f stages, and especially with a-m–f-m receivers where high-gain tubes and three i-f stages may be necessary in f-m reception and where it is desired to avoid the switching that would be required to reduce the number of i-f stages in a-m reception, lower gain on the 455-kc i.f. is needed to avoid instability, and inductance values as low as 200 μh are used.

Unequal primary and secondary inductances, but with equal primary and secondary Qs, are recommended for 10.7-Mc operation. In this way only the tube and other distributed capacitance need be used to tune the primary, while 50 $\mu\mu$f or more can be used for the secondary. Under these circumstances the primary circuit will give high gain and the secondary circuit will accommodate the change of as much as 2 $\mu\mu$f in the input capacitance of the following tube over the range of a-v-c action. A coupling slightly under optimum is recommended.

As i.f.s of 10 Mc and higher are considered, the gain which can be obtained is limited by one of three factors. One of these is band width, the difficulty being that if the gain is increased beyond a certain point, the band width will be narrowed; *i.e.*, for a given band width, other conditions being the same, there is a limit to the gain. The second limiting factor is stability, which depends on the grid-plate capacitance. If the gain exceeds a certain amount, sufficient voltage will be fed back to produce regeneration or oscillation. The third factor which may limit the gain is the input loading of the following stage. The losses due to transit time, cathode-lead inductance, and other causes are equivalent to a relatively low resistance shunted from grid to ground across the input of the following stage. This limits the gain that can be obtained.

74. Special I-f Coupling Systems. I-f transformers of various special kinds have been proposed or used in limited numbers.

Single-tuned transformers, with very closely coupled windings one of which is tuned, are less expensive than double-tuned designs and can be used where a limited amount of selectivity is sufficient. A triple-tuned design, having three windings and three capacitors, gives very good performance with a relatively wide flattop and sharp skirt selectivity. This type has been used to a limited extent with push-button receivers, the wide top accommodating some drift.

An interesting i-f coupling of a resonant mechanical type[1] is available, in which the mechanical equivalent of a band-pass filter is obtained by the use of small resonant metal plates or cylinders with suitable mechanical coupling elements. A typical design has a pass band of 8.5 kc, but affords an attenuation of 60 db at 10 kc away, *i.e.*, with a band width of 20 kc. Coupling into and out of the mechanical filter is by means of nickel magnetostrictive elements.

Another special class of i-f transformers is made for variable selectivity, usually having an additional winding which can be switched in or out to vary the coupling and thereby the band width. Further data on variable selectivity are given in Sec. 151.

For very sharp selectivity, such as for telegraph reception, a quartz-crystal filter is often used in the i-f amplifier. A description of this feature is given in Sec. 176.

W., Electro-mechanical Filters for 100-Kc Carrier and Sideband Selection, *Proc. IRE*, **44**, 14, January, 1956. Lapin, S. P., Electro-mechanical Filters, *Proc. Natl. Electronics Conf.*, **9**, 353, 1953. Doelz, M. L., and J. C. Hathaway, How to Use Mechanical I. F. Filters, *Electronics*, **26**, 138, March, 1953.

The use of band-pass filters, including M-derived sections,[1] affords sharp skirt selectivity for receivers in point-to-point practice. The over-all band width of one such amplifier measured 12½ kc at 6 db and only 19 kc at 90 db.

75. Proportioning of A-v-c Bias. In intermediate amplifiers of more than one stage, it may be advisable to reduce the amount of a-v-c bias applied to the last stage. This stage has the function of delivering the full amount of signal desired at the detector and should, therefore, not be biased back farther than this function permits. Otherwise distortion will be introduced, especially for high values of modulation.

76. I-f Amplifiers Using Transistors. The use of transistors in 455-kc i-f amplifiers is discussed in Sec. 38. For lower i-f values, especially the 262-kc option for automobile receivers, transistors are readily usable. For higher i.f.s, such as the 1.6 Mc sometimes used in amateur practice and the 10.7-Mc standard value for f-m broadcast receivers, care is needed to choose suitable transistor types and suitable circuit arrangements with regard to coupling systems, neutralization, a.v.c., etc.[2]

77. Wide-band I-f Amplifiers. The i-f amplifier in receivers for television, radar, and pulse-type communication systems must handle a wide band of signal frequency components. This requirement is met by (1) the use of a high value of i.f. to keep the relative band width within reasonable limits, and (2) the use of stagger tuning or of selective feedback to afford a wider band than otherwise obtainable.[3]

As an example of stagger tuning, a radar-type system proposed as an aid to air navigation included a receiver with a 60-Mc i-f amplifier of seven stages tuned individually at 55, 60, or 66 Mc so as to give an over-all band width of 12 Mc and a gain of 85 db, or an average of 12 db per stage.

The use of negative feedback in a wide-band i-f amplifier[4] is illustrated by a 60-Mc design of six stages using 6AK5's grouped into a first triplet consisting of the first three stages followed by a similar second triplet. In each triplet the interstage couplings consist of very closely coupled transformers poled to deliver to the following grid a signal of the same instantaneous sign as on the preceding plate. The negative feedback is then obtained by connecting 33,000-ohm resistors from plate to plate, two such resistors being required in each triplet.

An improved pentode (type 404-A) having less noise and about twice the ratio of transconductance to the total of input and output capacitances in comparison with the 6AK5 is used in the 65-Mc i-f amplifiers in the 4,000-Mc relay system operating between New York and Boston.

Receivers for searching for enemy radar signals included designs[5] with high i.f.s. The highest reported was 300 Mc, the amplifier consisting of ten 6AK5 stages with stagger tuning. A band width of 20 Mc at the peak and 24.5 Mc at 6 db was obtained.

MANUAL AND AUTOMATIC VOLUME CONTROL

78. Manual Control. The function of the volume control is to reproduce the modulation at the desired loudness and preferably to maintain this loudness as the receiver is tuned to different stations of various field strengths or as the field strength of the tuned station varies because of fading. The almost universal general solution to these problems is the use of a.v.c. for securing the proper amount of h-f amplification

and the use of a potentiometer in the audio amplifier[1] for establishing the output volume. Ideally, this method produces a signal at the detector which has the same strength for all stations and fading conditions, so that after the audio volume control is adjusted, no further attention is required.

The manual volume control in a-v-c sets is almost always located between the diode detector and the first audio stage. Usually the one or two diodes for the detection and a triode as first audio amplifier are in a common envelope, *e.g.*, the 12AV6 and the 12BF6. The most common value of the volume control is ½ megohm, with 1 megohm also frequently found. In best designs, the return circuit from the diodes includes first a tweet filter of about 100 $\mu\mu$f followed by a resistor of 47,000 ohms followed by another 100-$\mu\mu$f capacitor, after which the circuit divides into the a-v-c bus and the volume-control potentiometer.

A capacitor is sometimes provided to prevent the flow of d.c. through the volume control, the aim being to increase the life of the volume control before noise develops. A capacitor is generally used in the lead from the arm of the volume control so as to prevent applying the a-v-c bias to the first audio stage.

A special effect as the volume control is reduced can be obtained with a tone-compensated design[2] in which the apparent strength of the low frequencies is maintained. In the absence of this feature, the low notes disappear and make music sound thin whenever the volume control is reduced. The circuit in Fig. 18 furnishes a path to ground for the higher audio frequencies which is more effective when the volume control is set at the lower positions; the relative strength of the bass notes is thus increased. Such bass-compensated tone controls have been generally found to afford more pleasing reproduction at low volumes and have therefore been widely used in medium- and high-grade receivers.

FIG. 18. Bass-compensated volume control.

Tone compensation for the high notes can also be provided, using the same fixed tap as for low-note compensation. For this purpose, a fixed capacitor is connected in shunt with the upper end of the volume control. This provides a path for the high audio frequencies, delivering them in greater amount at the fixed tap so that they are more effective when the volume is set low.

79. Automatic Volume Control. Practically all radio receivers now manufactured are provided with a.v.c.[3] Another name for this feature is *automatic gain control* (or *a.g.c.*). The usual practice is to employ gradual cutoff tubes for r-f and i-f amplification and a suitable type of converter so that the bias on all these tubes can be made more negative and the gain thus be decreased as the signal strength increases, the bias consisting of d-c voltage developed in a diode detector by the signal itself.

As discussed in Sec. 15, the extent to which an a-v-c system delivers uniform output for various input intensities is indicated by the "a-v-c figure of merit," which is the range in decibels over which the input can vary while producing a change of only 10 db in the output. For home receivers, the a-v-c figure of merit normally lies in the range of 40 to 55 db, being larger for the better receivers.

80. Typical A-v-c Circuits. Figure 19 shows the type of a-v-c circuit now in widest use. It is, of course, a compromise between performance and cost. In it one diode circuit and one load resistor are used to develop both the a-v-c bias and the audio out-

[1] EIA, Standard REC-121-B, "Variable Control Resistors," February, 1953; covers standard values, tapers, taps, tolerances, and mechanical details.

put; *i.e.*, a common detector is used for both a-v-c and audio requirements. In operation, the positive peaks of the i-f signal on the diode plate attract electrons from the cathode. These flow through the secondary winding of the i-f transformer, through the 47,000-ohm filter resistor, and through the ½-megohm volume control, returning to the cathode. When modulation is present, this flow of electrons has both d-c and

FIG. 19. Typical a-v-c circuit in five-tube receiver.

a-f components. The desired amount of a-f voltage is picked off by the tap and applied to the grid of the triode which serves as the first audio amplifier. The rectified d-c voltage across the 500,000-ohm diode load acts through the 2.2-megohm filter resistor in the a-v-c bus to determine the grid potential of the two h-f tubes which are controlled. As the signal strength at the antenna increases, more signal will be rectified by the diode, and a greater negative bias will be applied to the two controlled tubes. This change of bias reduces the gain of these tubes with the result that the output of the receiver changes by a much smaller ratio than the input.

FIG. 20. Essential features of "gas gate" in an a-v-c circuit.

81. Use of Gas Gate with A.V.C. Extensive use is made of a circuit feature called a "gas gate," which offers insurance at negligible expense against a certain type of trouble. Sometimes the converter tube, especially in sets having an r-f stage followed by an untuned coupling, will develop sufficient ionization so that positive ions going to the control grid and thence flowing to ground through the high bias resistor will maintain such a large positive d-c drop in the bias resistor (30 or 40 volts) that the tube will draw an excessive sustained plate current and damage will result. This condition can occur with tubes which are normal as indicated by all the usual tests and circuit applications. The gas gate, as shown in Fig. 20, normally employs the second diode plate and connects it to the a-v-c line on the side of the filter resistor which is toward the grid return of the converter stage. Under these circumstances, any positive potential on the grid causes a flow of current through the low

forward resistance of the gas-gate diode, which prevents the grid from going appreciably positive. Television engineers will recognize the similarity of this to the reinserting diodes used in studio and receiving equipment.

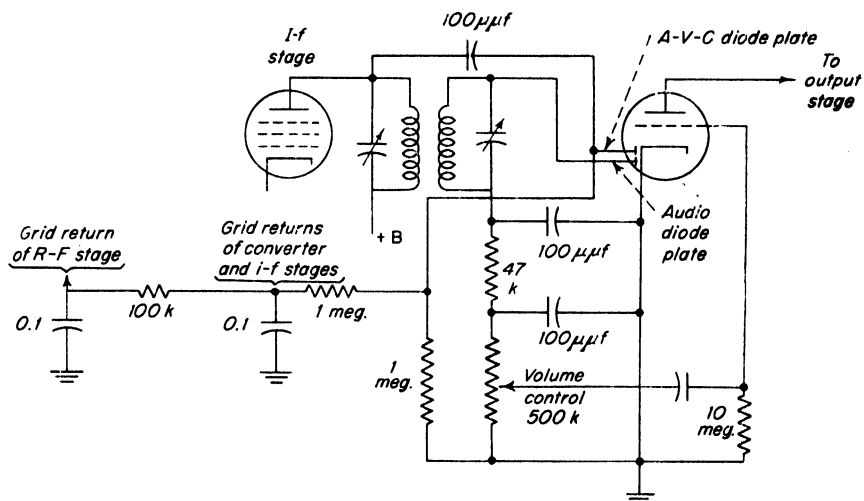
82. Different Selectivity for A-v-c and Audio Detection. Figure 21 shows the use of separate diode plates for the a-v-c and audio detection. This allows the a-v-c diode plate to be supplied with signal from a point in the receiver which is preceded by less selectivity than is used ahead of the audio detector. In fact, the a-v-c diode is supplied from the primary of the last i-f transformer while the audio diode is supplied from the secondary. The advantage of this arrangement is that, when the receiver is tuned through a station, the bias voltage is held about constant so that the station "naturally" becomes louder owing to the additional selectivity in the audio


FIG. 21. Use of separate diodes for a-v-c and audio detection.

detector channel and then fades out, permitting easy adjustment of the tuning. Also the large amount of noise heard near each station is reduced. The difference in the signal strength in the two channels should not exceed 20 db. Otherwise the sensitivity in the neighborhood of a strong station may be reduced to the point of preventing the reception of a weak station on the next channel.

In Fig. 21 the a-v-c diode is supplied through a capacitor of 100 μμf and has a load resistor of 1 megohm. No filter capacitor can be connected at this diode because it would detune the primary of the transformer. Instead, filtering is provided by a series resistor of 1 megohm and a 0.1-μf capacitor, after which the control bias is delivered to the grid returns of the converter and i-f stages. Additional filtering is provided for the lead which delivers bias to the r-f stage.

83. I-f Filtering. It is necessary that the i-f signal at the detector be prevented from proceeding on into the audio amplifier and also from going back into earlier stages of the receiver. The presence of i-f signal in the audio amplifier is objectionable because of (1) the likelihood of producing overloading with consequent audio distortion, and (2) the increased probability of feedback of the i-f fundamental or its harmonics into the r-f or i-f stages. Feedback into these earlier stages can occur directly from the detector in various ways, such as due to poor placing of parts, lack of shielding, or need for increased filtering such as for the a-v-c bias line. Feedback to the r-f circuits will produce whistles (or tweets) on stations having frequencies near the har-

monics of the i.f. Feedback of the fundamental into the i-f circuits will produce instability.

To confine the i-f signal the circuit of Fig. 19 includes a filter in the diode plate return consisting of two 100-$\mu\mu$f shunt capacitors and a 47,000-ohm series resistor. This filter greatly reduces the amount of i-f signal getting either on the a-v-c line or on the first audio grid. In Fig. 21 a similar filter is provided in the audio circuit and increased general filtering is included in the a-v-c line.

84. Delayed A.V.C. All the a-v-c circuits just described are subject to the objection that a fairly weak signal will develop some negative bias in the load resistor of the a-v-c diode circuit and thereby reduce the r-f amplification to some extent, all under conditions where the full amplification and the maximum output from the receiver are desired.[1] Various systems have been devised which prevent this effect. In terms of a signal of increasing field strength, these circuits delay the start of a-v-c action until the output has reached a volume as great as desired. The name "delay" is, therefore, with regard to increasing field strength and not with regard to time.

Fig. 22. Various a-v-c characteristic curves.

The difference is shown in Fig. 22 where curve *A* is the characteristic which the receiver will have without any a.v.c. The curve *B* is the characteristic with simple a.v.c. The curves *C* and *D* show the characteristics obtained with delay, more stages being controlled in the case of *D* than with *C*. Curve *E* is the ideal, where the output is uniform above the necessary minimum value of signal strength.

85. Biasing Controlled Tubes in Different Amounts. To minimize a type of distortion frequently encountered due to curvature of the characteristic of amplifying tubes, it is desirable as a general principle to proportion the a-v-c bias on the various tubes so as to have less bias on those operating at higher signal levels.

This is a refinement found in the better receivers. The method consists of a tap on the a-v-c load resistor so that, *e.g.*, in the case of two i-f stages, the last i-f stage receives only half the bias applied to the other tubes of the receiver. The cost consists chiefly of one additional resistor and capacitor for filtering the new a-v-c line.

86. Separate A-v-c Amplifier. For very high-grade performance, such as in communication receivers and in point-to-point practice, a separate a-v-c amplifier should be provided. In one form this consists of a separate i-f amplifier followed by a separate diode, so that greater negative biases are obtained and a flatter a-v-c curve is secured. In the other form the a-v-c bias is obtained in the usual way, and the separate a-v-c amplifier consists of a d-c amplifier which increases the magnitude of the bias voltage before application to the controlled tubes.

The usual a-v-c system is sometimes described as "regressive" to indicate that the control bias is applied to tubes earlier in the circuit than the point at which the diode is located. In distinction to this, the term "progressive" is sometimes used to describe any system in which control bias is applied to one or more tubes located farther along in the circuit than the point where the signal is taken off to operate the a-v-c system. The progressive method can sometimes be advantageously employed where a separate i-f amplifier for a-v-c is provided. A very flat a-v-c curve, *i.e.*, a very high a-v-c figure of merit, is obtained in this way, but care has to be taken to avoid applying too great a bias to the last controlled tube where the signal level may be high. Also, there is a possibility that the a-v-c curve may drop below the hori-

[1] An interesting discussion of remedies for this in point-to-point practice is given by John B. Moore, AGC Noise Considerations in Receiver Design, *Electronics*, May, 1945, p. 116.

zontal, so that the receiver may give less output for greater input signals, if this method is carelessly applied.

Another a-v-c arrangement that will give a very flat a-v-c curve has been used in point-to-point telephone practice[1] and is shown in Fig. 23. In this circuit the a-v-c detector following the a-v-c amplifier provides negative bias for the controlled stages but is also arranged to deliver positive bias to the a-v-c amplifier. The benefit of this positive bias connection can be seen if we suppose that a very large signal is being received and that the output of the set would otherwise be more than desired. The effect of the positive connection is to increase the amplification in the a-v-c amplifier, thus making the a-v-c bias more negative and producing the desired reduction in the amplification of the controlled stages. Conversely, when the signal input is very weak, the positive and negative biases delivered by the a-v-c detector are small so that the gain of the a-v-c amplifier, with a small positive relative bias, is small, with the result that the controlled tubes operate at or near full gain.

Fig. 23. Use of positive bias in the a-v-c amplifier to obtain very flat a-v-c characteristic.

87. Gain-time Control and Gated A.V.C. In radar receivers the irregularity and the uncertainty of the return echoes make the employment of a.v.c. undesirable, and two other types of operation are used instead. One of these is gain-time control (GTC), in which after each outgoing pulse the receiver is brought up to full sensitivity at a definite rate so that gain increases as a function of time. In this way the powerful echoes from nearby objects are attenuated while echoes arriving later from distant points find the receiver at full sensitivity and are thereby adequately reproduced despite the weak intensity of these echoes. Gain-time control is generally used, for example, to operate a PPI (plan and position indicator) type of oscilloscope, which is the most widely used means of radar presentation.

Some radars are designed to track a given target, such as an airplane, after they are once trained upon it. For this purpose a.v.c. can be used, provided the particular return echo is isolated and used as the control signal. This isolation is accomplished by means of a "gate" which is a time-sampling process by which, at the particular moment when the echo is arriving, the output of the receiver is routed into the a-v-c diode. Here a suitable control bias is developed as in the usual a-v-c circuit. Manual or automatic means are provided so that the timing of the gate is varied to hold the desired target as it varies in its location. Gated a.v.c. therefore operates to control the gain with regard only to a signal arriving at a definite time following the transmission of the outgoing radar pulse. By means of gated a.v.c. the strength of the particular echo can be held constant, independent of wide variations in the intensity of the echo as received on the antenna.

The transmission of radar signals through the usual wave guides makes available an additional means of amplitude control in the form of Faraday-effect rotation of the plane of polarization produced by a d-c magnetic field applied at a ferrite body in the wave guide.[2]

TUNING INDICATORS

A tuning indicator is a device to show visually when a receiver is accurately tuned to a station. Various forms of indicators have been used and two of these are still extensively employed. Those now used are (1) a milliammeter in the plate circuit of
[1] Black, D. M., G. Rodman, and W. T. Wintringham, Ultra-short-wave Receiver for the Cape Charles-Norfolk Multiplex Radiotelephone Circuit, *Proc. IRE*, February, 1945, p. 98.

[2] Vinding, J. P., An Automatic Gain Control System for Microwaves, *Trans. IRE*, **MTT-4**, 244, October, 1956. Loss, M. B., Broadband Applications of Ferrites, *Tele-Tech and Electronic Industries*, **15**, 62, February, 1956.

one or more tubes controlled by a.v.c. and (2) the electron-ray tube, a special form of small cathode-ray tube acting as a voltmeter to indicate when the bias on the a-v-c line reaches its greatest negative value.

88. Meter as Tuning Indicator.[1] The earliest form of tuning indicator, provided in the first a-v-c sets, was a milliammeter showing the current in the controlled tubes. This form is still in general use for communication receivers. Such a meter is often graduated in *S* units to show signal strength according to practice in amateur radio.

89. Electron-ray Indicator Tubes. Various types of small cathode-ray tubes specially constructed for use as tuning indicators have been produced. The most widely used is the 6U5/6G5, which produces a sector-shaped pattern with a total opening of 90 deg when there is zero voltage on the control grid, the angle closing gradually to zero as more negative biases are applied to the control grid. The pattern is completely closed at a potential at −8 volts if the plate supply is 100 volts, at −18.5 volts if the supply is 200 volts, and at −22 volts for a supply of 250 volts. A built-in d-c triode amplifier is included in this electron-ray tube. A-v-c voltage is applied to the grid of the amplifier, which produces an amplified positive voltage on a deflecting electrode internally connected to the triode plate.

90. Advantage of Tuning Indicator. Whether or not to provide a tuning indicator in a given receiver is a question which the engineer may have to consider carefully. For an a-m receiver designed to give high-fidelity reproduction, a moderately wide flat-topped response is desirable, and a tuning indicator should be included so that stations can be accurately tuned to the center of this region, where conditions will be best with regard to freedom from interference. For a high-grade f-m receiver, a tuning indicator should also be provided, especially because, when the set is tuned, the program is generally at a medium or low modulation level, and the general user may have little way of knowing when the tuning is accurately centered. With an f-m set, centering the tuning is more important than with an a-m set because, when loud passages of the program occur in the f-m transmission, the frequency swings over a large part of the 150-kc total deviation. The 6AL7GT tuning indicator has three separate deflector electrodes and allows independent display of the i-f tuning and the discriminator tuning, or other arrangements utilizing the versatility of the tube.

91. The 6AL7GT Electron-ray Tube. This tube[2] with three deflecting electrodes has in addition a control grid which can be used to vary the brightness of the display. This tube does not have a built-in amplifier, but its sensitivity amounts to 1 mm height of display per volt. The display consists of two columns of fluorescence each going upward or downward from a central reference point. The two upper portions are separately controlled by two deflecting electrodes, and the two bottom portions are controlled in step by the third electrode. The grid characteristic has a cutoff at −6 volts, giving rise to the possibility that an indicator-squelch feature can be incorporated so as to darken the display between stations.[3]

92. Other Indicator Tubes. An attractive flared pattern for viewing from the side of the tube is offered by the Philips Type EM 80, which has a heater rated at 6.3 volts and 0.300 amp. Much similar, but with a single sector pattern, is the Lorenz EM 85.[4] Both these types have an over-all length of approximately 2⅝ in. (67 mm).

SQUELCH AND NOISE-LIMITING CIRCUITS

Two methods for combating noise are squelch and noise limiting. Either or both may be used in a given receiver, and both should be considered in special-purpose

designs. Extensive use of both features is made in police receivers, and noise limiters are generally included in receivers for the communication service.

93. Squelch Circuits. Various terms are used to designate squelch circuits, such as quiet automatic volume control (or QAVC), muting systems, and codan (*C*arrier-*O*perated *D*evice *A*nti-*N*oise).[1] The purpose of these circuits is to squelch or quiet the receiver when sufficient signal for satisfactory reception is not present. Where the transmission is not continuous but the receivers must always be ready for a signal, as in police service, a squelch circuit performs the important function of removing the large amount of noise which might otherwise be present between transmissions. In receivers for broadcast reception and other services in which tuning through a wide band is necessary, the squelch feature affords the additional benefit of interstation noise suppression.

Considerable care in the design of a squelch circuit is necessary to avoid "ragged-edge" effects when the signal fluctuates rapidly between acceptable and nonacceptable values.

A squelch circuit consists essentially of suitable means for (1) assessing the reception conditions and (2) disabling the receiver as long as satisfactory reception is not possible. The assessing is generally on the basis of conditions in the i-f amplifier, and the disabling is usually accomplished by biasing a grid of the audio amplifier beyond cutoff.

The assessing function of a squelch circuit in an f-m system can utilize the rectified limiter grid current, as representative of signal strength, tending to remove the squelch and let the set operate. At the same time a noise signal of audio frequencies above the transmitted voice range can be rectified and used in the direction of applying the squelch. In police service, when the station carrier comes on for a transmission, the limiter voltage in such a set increases, and the rectified noise voltage decreases; since both effects act to remove the squelch, the receiver becomes operative.[2]

For the application of the large squelch bias a d-c amplifier called the "squelch tube" is generally used. It is ordinarily a triode. The flow of plate current in the triode causes a voltage drop in the plate circuit, and the connections are so arranged that this voltage drop biases the first audio amplifier beyond cutoff, thus squelching the set. Conversely, when the squelch tube is cut off, the first audio stage operates and signals are received.

Since receiving conditions vary, especially with regard to the amount of man-made interference in the locality, an adjustment is provided to control the level required by the squelch to let the set operate. In this way, when interference is slight, the sensitivity and range of the receiver can be increased. Under the best conditions a signal of 140 db (0.1 μv) is sufficient to open the squelch of a police receiver, and the range of adjustment in a typical set is 140 to 128 db (0.1 to 0.4 μv).

Fig. 24. Simple noise limiter of shunt type for headphone use.

94. Noise Limiters. Various arrangements[3] of diodes, multigrid tubes, and other elements are available for limiting the amplitude of noise peaks or disabling the receiver for very short periods while high-amplitude noise is present.

A simple limiter,[4] shown in Fig. 24, utilizes two 1N34 germanium crystals. Each crystal is biased by a dry cell so poled that the crystal becomes conductive whenever the amplitude exceeds the 1.5-volt potential of the cell. The maximum a-c signal

[4] Grammar, George, Noise Limiting in C. W. Reception, *QST*, May, 1946, p. 13.

at the phones is therefore 0.7 × 1.5, or about 1 volt rms. This limiter is reported to give good results in the reduction of impulse interference, such as automobile ignition, if care is used in the adjustment of the audio and radio volume controls.

Another limiter, widely used in police receivers and in naval shipboard receivers, is discussed in the Toth reference and shown in Fig. 25. This consists of a diode in series with the outgoing audio lead and having such a polarity that it cannot pass the large negative impulses resulting from the rectification of an intense noise train by the detector diode. The operation may be described briefly by saying that a large noise pulse from the i-f transformer, having peaks of both positive and negative polarities, loses the negative peaks in the regular diode detector, and loses the excess positive peaks, now rectified into a negative peak, in the series limiter diode.

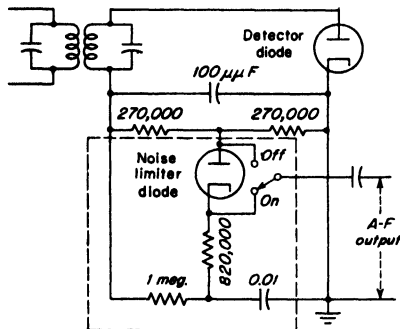
The operation of this limiter depends on time constants and particularly on the fact that the cathode of the series diode requires about 200 times longer to change its potential by a given amount than the plate. A sudden negative peak on the plate therefore merely makes the plate greatly negative with respect to its cathode, renders the diode nonconductive, and temporarily open-circuits the audio output connections. By the time the cathode has made a slight start in the negative direction, the noise peak is over and the limiter has served its purpose. For example, the normal potential of the plate may be about −5 volts and the cathode about −7 volts. A noise pulse carrying the plate to −50 volts obviously makes the diode go on open circuit, removing most of the effect of the noise pulse from the output circuit.


Fig. 25. Series-diode noise limiter.

In summing up a review of several types of noise limiters, Toth concludes that from the standpoint of simplicity, effectiveness, and low distortion, the series-diode type appears best for voice and m-c-w operation. For c-w operation the full-wave a-f shunt type (such as Fig. 24 with the possible substitution of vacuum diodes for the crystals) appears best because of simplicity, effectiveness, and minimum change of gain below the limiting threshold. Both types can be used in c-w service. The benefit of these limiters is greatest where the noise peaks substantially exceed the desired carrier peak values.[1] If this is not the case, only some very elaborate types will afford much relief.

Receivers operating near radars can be blanked by utilizing trigger pulses from the radars. Each of these pulses is properly delayed, and they are then combined and used to disable the heterodyne oscillators of the receivers.[2]

TONE CONTROL

95. Purpose and Types.[3] The low cost and utility of a tone control have made it a common feature of broadcast receivers. It can be defined as any control by which the user can vary the amplitude-frequency characteristic of the audio amplifier of the receiver. Its usual form consists of a simple h-f attenuator. To the average

listener such a tone control offers the advantages of reducing (1) the worst effects of atmospherics or man-made interference and (2) the high-pitch content of the program if desired.

A survey of 31 models produced during the first two years of the postwar period showed 17 to have tone controls. These consisted of 7 with a series fixed capacitor and variable resistor, 7 with switched arrangements of two to four positions, 2 with independent knobs for bass and treble control, and 1 with multiple push buttons marked for treble, voice, normal, and other types of effects.

The conventional circuit consists of 0.002 to 0.05 μf in series with a variable resistor whose maximum value is usually 500,000 ohms. This circuit is connected from a plate or grid in the audio amplifier to ground or to B+, so as to introduce the desired amount of loss for the higher audio frequencies.

The switched arrangements ordinarily consist of two or three elements, *e.g.*, one capacitor and a fixed resistor so connected that the two may be used in series, or the capacitor only may be put in circuit, or neither may be used.

In high-class receivers, there is an increasing trend toward the provision of separate controls for the bass and treble. The treble control can be similar to the series circuits with a variable resistor as already described. Designs including separate bass and treble controls can be made utilizing negative feedback arrangements. Feedback for tone-control uses may be taken from the high side of the voice coil or from the unbypassed cathode of the output stage, and can be brought back so as to introduce a voltage in series with the volume control at its low-potential end. Series or shunt resistors or capacitors associated with the feedback connection make it possible to obtain desired audio characteristics. A tone-compensated volume control can be included in the circuit at slight extra expense.

AUTOMATIC FREQUENCY CONTROL (A.F.C.)

96. Basic Functions. A radio receiver, already tuned approximately to a given signal, can be automatically brought to almost perfect tuning and be maintained there by means of a.f.c.[1] Drift in the frequency of the superheterodyne oscillator due to warmup can thus be compensated, and also tuning errors due to poor manual adjustment or to inaccuracies in the operation of push-button tuners.

An a-f-c circuit consists of two main parts: the *discriminator* and the *control device.* The discriminator is an error detector and determines the direction and amount of the frequency error to be corrected. The output of the discriminator goes to the control device, which is generally a *reactance tube.* The plate circuit of the reactance tube is made to have a reactive character of controllable amount, so that by connecting it across the oscillator tuned circuit the desired control of the oscillator frequency is obtained. The r-f antenna and interstage circuits are made wide enough not to require correction.

The error found by the discriminator is that existing between the actual signal in the i-f amplifier and the center frequency of this amplifier. The correction made in the oscillator frequency is such that the r-f signal is converted into an i.f. which is much closer to the proper value. Perfect or complete correction with the reactance tube as a control device is not possible because some error is necessary to produce the discriminator output to control the reactance tube. However, this is unimportant in practice because sufficiently complete correction is easily obtainable.

97. Discriminators. The most widely used discriminator[2] has been the coupled-circuit system, also called the phase-variation type, in which the primary voltage is delivered to the center of the secondary, so that the secondary terminals furnish to two diode plates the primary voltage in the same phase on the two plates and the secondary voltage in opposing phases. Both primary and secondary circuits are tuned to the i.f., and this is the frequency which the discriminator uses as its standard of

reference. The essential a-c connections and the action are shown in Fig. 26, where it can be seen that (1) at resonance the two diode plates have equal amounts of signal ($E_{CD} = E_{AD}$); (2) below resonance, plate C gets more signal (E_{CD}) than A; and (3) above resonance, A gets more signal (E_{AD}). This action results from the phase relations normally occurring in two inductively coupled tuned circuits. To obtain a d-c output from the discriminator it is only necessary to add the d-c voltages from the two diodes in a series-opposing connection. The resulting single output then has a polarity indicative of the direction of the error and an amount indicative of the extent of the error.

In f-m receivers with a.f.c., a single discriminator can usually be arranged to produce audio signal, a-f-c output, and a-v-c bias. If only a-f-c output is required, there is
FIG. 26. Action of coupled-circuit discriminator.

greater latitude for proportioning the time constants to secure just the kind of a-f-c action desired. Requirements vary depending on whether the receiver is for fixed-frequency or variable-frequency service, the value of the a-v-c time constant, and whether high-fidelity audio output is required.

For further material on discriminators the reader is referred to the general discussion of f-m detectors in Secs. 140 and 141 and in Chap. 12.

98. Reactance Tubes. The actual shift of oscillator frequency is made by the reactance tube, whose plate circuit is connected across the tuned circuit of the oscillator. The connections can be arranged for the reactance tube to add either inductive or capacitive reactance in parallel with the oscillator tuned circuit. Inductive reactance in parallel raises the oscillator frequency, while capacitive reactance in parallel lowers it.

To obtain a reactive plate impedance, the a-c plate voltage and plate current must be 90 deg out of phase with each other. The plate voltage comes from the oscillator and can be taken as establishing the reference phase. It is necessary that the current be in quadrature with this. Since the current is determined by the grid voltage, the grid and plate voltages must be in quadrature. An RC phase splitter will accomplish this. For example, a small capacitance connected from plate to grid and a small resistor from grid to ground will furnish a circuit from plate to ground which will have an almost pure capacitive reactance. The oscillator voltage will therefore drive a leading current through this circuit. The grid

voltage, being the drop in the resistor, will also lead, and therefore the plate current will lead, all with respect to the alternating plate voltage applied by the oscillator. Since the plate current leads the plate voltage, the plate impedance is capacitive, and the desired control of frequency is obtainable. Ideally C and R in the phase splitter are exceedingly small, and a perfect 90-deg phase shift is obtained. It is desirable that this shift be reasonably near 90 deg so that the plate current contain no substantial component in phase with the voltage. This would represent a loss across the oscillator tuned circuit with the additional objection that it would vary with the amount of frequency correction at the moment.

The magnitude of the capacitance added by the reactance tube in the case just described is approximately $g_m CR$, where g_m is the transconductance of the reactance tube under operating conditions including the bias received from the discriminator. For example, a 6SJ7 reactance tube operating at 1,000 μmhos, with a capacitor of 30 $\mu\mu$f and a resistor of 600 ohms, acts as a capacitor of 18 $\mu\mu$f across the oscillator tuned circuit.

Inductive reactance can be obtained from the reactance tube by exchanging the positions of the two elements, *i.e.*, by using a resistor (with large blocking capacitor in series) from plate to grid and a capacitor from grid to ground. In this case the desired 90-deg relation is most nearly realized with the largest practical values of the resistor and capacitor.

99. A.F.C. in Receivers for the Standard and F-m Broadcast Bands. During the years a limited number of manufactured models for the standard 1-Mc broadcast band have appeared with a.f.c., but ordinarily this feature has been deemed of less value than other improvements of similar cost. This applies to complete receivers and to tuners offered as units for high-fidelity installations. (Automobile receivers of the "signal-seeking" type, as produced since about 1950, include a frequency sweep which carries the tuning up the frequency scale but is subject to automatic stopping whenever a signal is found. These designs do not include a.f.c., and are therefore discussed elsewhere—see Sec. 153.)

An experimental design has been made for the 1-Mc broadcast band using a.f.c. and a sweep feature. In this design the change of stations is made by change of inductance produced by altering the d.c. flowing in an auxiliary winding around the core of suitable saturable material. The permeability of the core is varied by the d.c., and thereby the inductance is changed.[1]

The provision of a.f.c. in an f-m broadcast receiver meets in a very convenient manner for the user the need for accurately tuning to the center of the assigned channel. A tuning indicator is a less convenient method of meeting this need. The reason for this need is that on moderate program levels the signal occupies only a fraction of the channel so that the receiver may unwittingly be mistuned and the listener observe bad quality when high levels occur. Tuners for f-m reception in high-fidelity installations therefore often include either an a-f-c circuit or a tuning indicator.

In an f-m receiver or tuner the control voltage for a.f.c. can be obtained from the f-m detector already in the receiver. It is necessary only to provide the reactance tube and a few resistors and capacitors. An economical solution is to employ a dual triode in which one triode acts as oscillator and the other as reactance tube. The system can be adjusted so as to reduce the tuning error to only $\frac{1}{5}$ to $\frac{1}{10}$ of its previous value.

100. A.F.C. in V-h-f and Higher-frequency Service. The introduction of narrower channels for such services as radio extension of the normal wire telephone system to automobiles has made a.f.c. a necessary feature. Similarly it has been found desirable in receivers for police, fire, and other emergency services. Figure 27 shows the reactance tube and the oscillator-tripler in the General Electric Model 4-ER-4A-1 receiver, designed for fixed-frequency f-m operation on any channel from 152 to 162 Mc and for installation in either cars or headquarters stations. This receiver is a double superheterodyne in which the twenty-seventh harmonic of the crystal is used to reduce the signal to the first i.f. of about 17 Mc. The third harmonic of the crystal is used in the second mixer to produce the second i.f. of 2 Mc. The dis-

[1] Hargens, C. W., III, An All-electronic Signal-seeking Broadcast Receiver, *Trans. IRE*, **BTR-1** (4), 5, October, 1955.

criminator and the general design are arranged for holding the 2-Mc i-f signal centered on the discriminator characteristic.

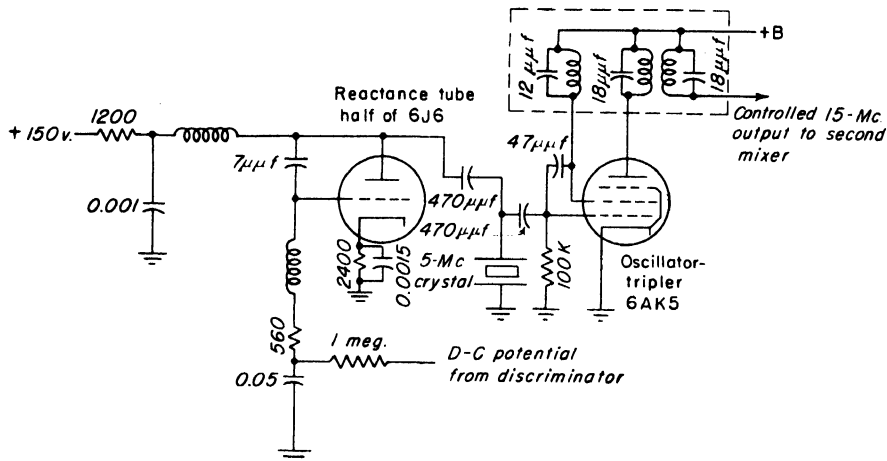
The 6AK5 oscillator-tripler, shown in Fig. 27, produces the third harmonic for the second mixer. This harmonic is also used after a further multiplication of nine times as the heterodyne frequency for the first mixer. It is slight variation in this third-harmonic frequency of approximately 15 Mc which automatically keeps the receiver in tune and compensates drifting in either the transmitter or the receiver. Without this a-f-c feature, temperature control of the transmitting and receiving crystals would be necessary. The reactance tube in Fig. 27 is half of a 6J6 triode whose plate resistance is increased by operation at a considerable negative grid bias so as not to damp the crystal excessively. As receiver design has proceeded into the u-h-f and s-h-f ranges, a compelling need for a.f.c. has been found. To accommodate the unavoidable drift of the various oscillators, the alternative has been to increase the band width with the


FIG. 27. Use of a.f.c. with crystal oscillator in police receiver.

serious objections of reduced gain and increased noise. Radars and relay systems in these frequency ranges, therefore, make extensive use of a.f.c.[1] One purpose is holding the tuning during warmup, which may be quite important because normal operation may be required very soon after starting the equipment.

Klystrons acting as superhet oscillators can be controlled in frequency by variation of the d-c potential on the reflector electrode. Thus no reactance tube is required, but instead a d-c amplifier to give sufficient values of the voltage to be applied.

The i.f. in receivers for these frequency ranges is generally in the v-h-f band and often is 30 or 60 Mc. A coupled-circuit type of discriminator can be used.

Corrections of as much as 25 Mc may be required and are secured in these services.

101. Mechanical A.F.C. In a mechanical type of a.f.c. the discriminator output polarity determines the direction in which a correcting motor turns, rotating a small air capacitor to the proper point or otherwise making the necessary frequency correction. By gearing the motor down, high accuracy can be obtained. Mechanical a.f.c. has two advantages: (1) the "permanent" nature of the correction, since it does not change in the event of a long fade of the signal—when the signal returns, the tuning is the same and no reestablishment of the correction is required—and (2) perfect correction obtained because the existence of a small error is *not* necessary to maintain the

[1] Jenks, F. A., Simplified Microwave AFC, *Electronics*, November, 1947, p. 120; and December, 1947, p. 132. Miller, Stewart E., Considerations in the Design of Centimeter-wave Radar Receivers, *Proc. IRE*, April, 1947, p. 340. See section on a.f.c. in R. V. Pound, "Microwave Mixers," McGraw-Hill, 1948.

correction. The moving element rotates whenever any appreciable error exists and continues until the error is fully corrected.

The mechanical method of a.f.c. has been used in point-to-point practice[1] and also in radar service.[2]

102. Use of A.F.C. in Double Superhets. The use of a.f.c. in tunable receivers, as for the conventional broadcast band, requires some compromise by the designer to cover from 550 to 1,600 kc (oscillator 1,005 to 2,055 kc). For fixed-frequency service this compromise is not required. Also in double superhets the a-f-c correction can be made on the oscillator supplying the mixer between the two i.f.s, which is a constant-frequency oscillator except for this correction. In these cases very good a-f-c performance can be obtained, especially with regard to the frequency intervals at which the system takes hold and lets go.

SHIELDING AND FILTERING

103. Practical Points. It is common practice to confine the r-f and i-f circuits in metal containers which provide both electromagnetic and electrostatic shielding. In some instances shielded leads are used to provide the connections to the grids or plates of amplifier tubes, but in general the necessity for such shielding is avoided by so locating these leads that they are sufficiently isolated electrically.

In the design of a new receiver the selection of shielding is mostly a matter of general experience and of cut-and-try work in the laboratory. The presence of a shield can around a coil reduces the inductance and increases the losses, so that allowance for these effects may have to be made in the design. For quite low radio frequencies a fair thickness of shield is necessary, the requirement being a thickness of a few times the depth of penetration[3] of induced eddy currents at the particular frequency. The depth of penetration is defined as the depth at which the intensity of the induced current has fallen to 37 per cent of its value at the surface. This figure is $1/e = 1/2.72$, where e is the base of natural logarithms. For aluminum at 100 kc the depth of penetration is 0.27 mm (0.010 in.).

Care must be exercised in locating the power transformer and filter reactor on the receiver chassis, since otherwise the electromagnetic field produced by these units may induce an appreciable hum voltage in the a-f circuits. It is desirable to keep these units separated from the a-f circuits as much as possible, and it is frequently necessary to determine experimentally the best location for these components by connecting them into the circuit with flexible leads and orienting them until a position is established which reduces the hum to the desired minimum.[4]

Resistance-capacitance filters are frequently used in the voltage supply leads for the tube electrodes to prevent coupling between points in the system which differ in signal potential and to provide additional filtering for the voltage fluctuations remaining at the output of the B-supply filter. The d-c drop which can be tolerated in a given circuit is frequently a limiting factor in the use of such filters. Filtering can be improved by dividing the maximum resistance value into two or three series parts and by-passing all junctions to ground. When RC filters are used in circuits in which the average current varies during the operation of the receiver, it is essential that the recovery characteristic of the filter be such that the voltage on the electrode can return to its normal value in approximately 1/10 sec; otherwise noticeable interruptions in the received program will be obtained when sudden changes in the average current occur.

[4] Langford-Smith, F., "Radiotron Designer's Handbook," RCA, Harrison, N.J., 1952; see pp. 1196–1201.

This problem is most frequently encountered when *RC* filters are used in the plate or screen circuits of tubes which are controlled by the a-v-c system.

CABINET

104. Purpose and Proportioning. The cabinet must fulfill three requirements:

1. It must house and protect the receiver chassis and loud-speaker mechanism.
2. It must provide sufficient baffle area for the loud-speaker to give the desired l-f response.
3. It must serve as a piece of furniture which will harmonize with the furnishings in the room in which it is to be placed.

Cabinets of wood, plastic, metal, and with leather finish have been found acceptable in the medium and small sizes. Wood and metal are suitable for large cabinets.

Certain proportioning of height and width, in connection with the size, shape, and location of dials and knobs, produces a pleasing appearance, while other proportioning of the various dimensions seems unnatural. A study of these questions has been made.[1]

An important cabinet matter is to avoid the occurrence of acoustic feedback which can arise in receivers capable of producing high power output. To avoid this feedback, the tuning capacitor frequently is flexibly mounted, with respect to the chassis, by means of soft rubber washers. The complete chassis in many receivers is also flexibly mounted in the cabinet.

Acoustic feedback is caused by the loud-speaker vibrations being transmitted to the tuning capacitor or some other circuit element which is thereby caused to vibrate sufficiently to detune the receiver intermittently at an a-f rate. If the proper phase relations exist between the loud-speaker vibrations and the variations in signal intensity which result from the vibration of the capacitor plates, sustained oscillations may be produced.

REMOTE CONTROL AND TELEMETERING

Numerous methods are available for the control of radio receivers at a distance and also for the use of radio receivers for controlling other equipment. A third application of remote control is telemetering in which a distant transmitter controls a local receiver so as to furnish an indication or record of conditions in the neighborhood of the transmitter.

105. Remote Control of Receiver Adjustments. The simplest form of remote control is flexible shafting,[2] which may have a length of 2 or 3 ft for the control of an automobile receiver or a length of 15 or 20 ft for the control of an airplane receiver.

S. S. White flexible shafting for this purpose has considerably less angular deflection under torque than the power type used for automobile speedometers. As an example, a remote-control shaft 0.188 in. in diameter (shaft diameter, not diameter of flexible casing) at a torque of 1 lb-in. has a deflection of 3.3 deg per foot of shafting for either direction of torque. The same size of power shafting under the same conditions has a deflection of 5 deg in the winding direction of the outer layer of the shaft and of 17 deg in the unwinding direction.

The "Flexible Shaft Handbook" gives the torsional breaking strength of the various sizes and types of remote-control shafting. For the 0.188 diam this is about 25 lb-in., so that with a safety factor of 2:1 the maximum working load would be about 12 lb-in. Smaller sizes are offered down to 0.117 in. diam, for which the breaking strength is 4.5 lb-in., corresponding to about 2 lb-in. maximum working torque.

Should the torsional deflection be too great, producing too much backlash, which may well be the case with a length greater than a few feet, gearing should be applied so that the shaft turns at a higher velocity and lower torque than would otherwise be the case. A ratio of 14:1 is common and much higher values are sometimes used.

[1] Van Dyck, Arthur, Dynamic Symmetry in Radio Design, *Proc. IRE*, September, 1932, p. 1481.
[2] "Flexible Shaft Handbook," 3d ed., S. S. White, Industrial Division, 1951.

Another widely used method of remote control is by synchros, which are rotatable machines[1] often called by the trade names Selsyn or Autosyn. One of these is used at each end of the system, with the rotors connected to the same single-phase power-frequency supply line. Each machine has a three-phase stator, the three wires from the one machine being carried the necessary distance and connected to the stator of the machine at the other end. No three-phase power supply is required. If the rotor of either machine is turned, the other rotor follows it closely. Small machines of this kind have been developed by Bendix[2] weighing only 4.25 oz each. A system of four of these machines furnishing control and repeat-back services requires only 15 watts from a 400-cycle power source. In this system, the control machines turn at 10 times the angular velocity of the hand crank and are geared down 600:1 to the remote tuning shaft. In this way the shaft is rotated through 180 deg by 30 complete revolutions of the hand crank. The repeat-back system is geared up 1:1.66 so that at the operating point the 180 deg of shaft rotation appears nicely spread out on a 300-deg dial.

Push-button tuning systems of certain types are adaptable to remote control. This is especially the case with motor-operated systems and with systems in which a rotary switch at the receiver progresses cyclically through various positions for the choice of particular stations. (See Sec. 61 *et seq.*)

In communication services, such as at airports, the level of interference is sometimes so high that it is advantageous to locate the receiving antennas and receivers some miles away. In this case, the telephone line used to deliver the audio signal from each receiver can also deliver d-c voltage to control a reactance tube[3] at the receiver and thus obtain an adjustment of the frequency of the superheterodyne oscillator over a limited range. In c-w telegraph reception, the same method can be used to adjust the beat-frequency oscillator to give the best audio note.

An alternative to the reactance tube, consisting of a coil whose permeability depends on the amount of d.c. in an auxiliary winding, has been described by Polydoroff,[4] who reported an experimental design with a frequency range from about 200 to 350 kc, *i.e.*, 75 kc either side of 275 kc. A similar design for 500 to 3,000 Mc has been reported by Stiber.[5]

106. Use of Receivers for Remote Control of Other Equipment. There has been considerable interest for a number of years in the radio control of model airplanes.[6] The typical receiver circuit on the model plane consists of a self-quenching super-regenerative one-tube receiver using the RK62 thyratron, whose filament is rated at 1.4 volts and 0.05 amp.

Extensive use of radio for the remote control of airplanes was made during the late war.[7] These included guided missiles[8] and also target planes for both aerial and antiaircraft gunnery.

A striking use of radio-controlled planes was made during the Bikini atom-bomb tests by both the Army and Navy, who flew such planes through the cloud above the blast for the collection of samples of the atmosphere to be tested for radioactivity. The Navy planes were modified fighters and the Army planes were B17's. The Navy planes took off from the aircraft carrier Shangri-La, flew through the atomic cloud and then were directed to the

island of Roi, a distance of 178 miles, as they were too radioactive to permit their return to the carrier. The remote-control equipment included 10 audio channels with filters and synchro motors for carrying out the various functions. In the same way unmanned boats were sent through the contaminated lagoon by radio to collect samples of the sea water while it was still too radioactive to be handled.

107. Telemetering.[1] A telemetering receiver is a local receiver which brings in signals from a distance representing certain measurements and reproduces these on local indicators or records. Such a receiver is a remote-control device in the sense that it operates the indicator or recorder under the control of the remote transmitter.[2]

An extensive technology exists in the field of detecting, processing, and recording the received telemeter signals. According to the modulation operations at the transmitter, the receiver must perform f-m, a-m, or p-c-m (pulse-code-modulation) detection of the signals conveyed on the carrier and the subcarriers. Also the use of magnetic tape or other form of recording is an important element.[3]

The development of advanced telemetering and remote-control equipment is of special interest in connection with transonic flight, as the unavoidable dangers are thus transferred from a human pilot to a remote-control robot, and the reports of the test are obtained immediately on the ground by telemetering.

MULTIBAND RECEIVERS[4]

A large number of broadcast receivers produced since about 1935 cover, in addition to the normal broadcast band, one or more ranges in the region from 1.6 to 30 Mc.

108. Receivers with H-f Bands. In most receivers with one or more h-f bands, separate coils are employed in the r-f system for each tuning range. A few receivers use single coils with taps for the various bands. When such coils are utilized, the unused portion of the coil is always short-circuited to avoid absorption of signal at higher frequencies. When separate coils are employed, the coils for two or more of the frequency bands are frequently wound on a single form. The coil windings differ considerably with the frequency range. Wire as small as No. 35 AWG is used in the inductances for the tuning range from 540 to 1,600 kc, while wire as large as No. 22 is used in some of the h-f coils. The turns on the h-f coils are usually spaced to minimize coil losses.

These multiband receivers are provided with a gang switch for simultaneously connecting the coils used for each tuning range to the associated tuning-capacitor gang and tubes. On "normal" h-f ranges (as distinct from band-spread ranges) two- or three-gang tuning is used, the circuits being the antenna coupling, the r-f interstage coupling if present, and the oscillator tuning. The band switch connects the proper coil into each circuit for the particular frequency range.

109. Control Knobs and Dials. Multiband receivers are sometimes equipped with tuning mechanisms that permit the user to change the drive ratio between the tuning knob and the variable capacitor from a normal value such as 10:1 to finer control such as 50:1. This higher ratio is helpful in tuning the receiver to an h-f station since the band covered in a single h-f tuning range may be over 10 times that covered from 540 to 1,600 kc.

Special tuning dials are necessary on these receivers since a separate scale is required for each tuning range. In some receivers all the scales are visible, regardless of the tuning range being used, and an indicator or lighting arrangement actuated by the

range switch knob designates the correct scale. On other receivers only the scale corresponding to the tuning range being used is visible. With this arrangement the dial scales are movable with respect to the dial opening, and the range switch is mechanically connected with the dial scales so that, as the tuning range is switched from one frequency band to another, the proper scale is moved into place.

110. Design of Band-spread Circuits. To the amateur radio operator, the use of band spread on the congested amateur bands is of great value. Likewise, the listener to international broadcasts is greatly assisted by the provision of spread bands for these frequencies. In remote parts of the world where there are colonies of American and European citizens dependent on these frequencies for regular broadcast services, the provision of band spread is quite important.

Various arrangements of capacitors and inductors can be used to spread out a relatively narrow band so that it will cover the entire dial of a receiver.[1]

It is often sufficient to provide fixed band-pass circuits for the antenna and interstage r-f couplings, so that only the oscillator circuit is varied as the tuning dial is operated. In this case, Foster and Mountjoy[2] point out that double-tuned antenna coupling gives higher gain and greater uniformity of gain than single-tuned coupling. Typical values for the voltage gain of such a single-tuned circuit covering a complete spread band without adjustment are about 20 db, whereas with a double-tuned circuit values of 24 or 25 db are obtained. In receivers not having an r-f stage, it may therefore be worth while to provide double-tuned antenna couplings on the band-spread positions of the band switch.

An arrangement has been provided in some American models by which two spread bands are accommodated on a single position of the band switch. The lower end of the dial, amounting to about 40 per cent of the total movement, gives the band spreading for one of the bands to be received while the upper 40 per cent gives coverage similarly for the other band. The 20 per cent of the dial between these two parts accommodates in a compressed manner the frequencies lying between these two bands. A special capacitor-plate shape provides these characteristics, the radius changing slowly over the two ends and rapidly in the region between the two bands.

The band-spread ranges on a receiver, to be most useful, must be direct-reading. Since a change of 10 kc at 10 Mc represents only $\frac{1}{10}$ of 1 per cent, it is evident that the stability requirements on the oscillator tuning are very strict. Special attention must therefore be paid to the effects of temperature, age, voltage supply, and other factors on the oscillator frequency to obtain sufficient stability to satisfy the requirements. If temperature-compensating capacitors are used, care is necessary to locate them on the chassis so that the rate of heat transfer to them is correct to match the oscillator drift.

RADIO-PHONOGRAPH COMBINATIONS

The wide interest of the public in phonograph reproduction since the latter years of the 1930's has made this feature one of the most important aspects of receiver design and production. Great numbers of radio-phonograph combinations have been sold, including both table model and console types. In addition, separate electric phonographs have been produced in large numbers, and there has been extensive production of wireless record players as attachments to sets not having phonograph provisions. Numerous technical points[3] have arisen in the design and production of this large

quantity of equipment, and various special designs have been marketed. The present section summarizes some of the chief engineering data and available methods in this field.

111. Constant-velocity Recording. There are two different fundamental types of recording, constant-velocity and constant-amplitude, a combination of which is generally used.[1]

In constant-velocity recording, if several frequencies are handled in turn by the recording amplifier and are at the same level, each will drive the cutting stylus with the same maximum velocity during each audio cycle. The reproducing stylus will then correspondingly be given the same maximum velocity at the various frequencies when the record is played. Ideally, the magnetic type of cutter produces a constant-velocity recording. This type of recording cannot, however, be used below about 500 cps because it is accompanied by an increase of amplitude which is inversely proportional to the frequency, with the result that the usual spacing of grooves would be inadequate. The crystal type of cutter will produce a constant-velocity recording if it is operated with a suitable network which introduces increasing attenuation at the higher frequencies.

FIG. 28. Arrangement for observing optical pattern of laterally cut phonograph record.

The intensity of recording on a record can be examined as shown in Fig. 28 by reflecting a light from the surface in the proper manner. The pattern seen is defined as the *optical pattern*, often called a "Christmas tree." It has a uniform width for frequencies recorded with the same velocity.[2]

A constant-velocity recording would in the ideal give a faithful reproduction if played with a magnetic pickup. When played with a crystal pickup, it would give faithful reproduction if a suitable network were used to introduce greater attenuation for the lower frequencies.

112. Constant-amplitude Recording. If various frequencies at the same level in a recording amplifier are so transferred to the record that they have the same maximum amplitude on the record, the type of recording and the record itself are characterized as constant-amplitude. A crystal cutter produces a constant-amplitude recording. With a magnetic cutter, a constant-amplitude recording can be obtained by the use of a suitable network with increasing attenuation at lower frequencies.

In constant-amplitude recording, the maximum velocity is proportional to the frequency since the needle must traverse the given amplitude in less and less time as the period is reduced accompanying the increasing frequency. For this reason the velocity with a constant-amplitude recording doubles each time the frequency is doubled. Therefore for each octave change to a higher frequency the constant-amplitude recording has a 6-db increase of velocity. This corresponds to 24 db greater velocity at 8,000 cps than at 500 cps. This can be considered as a substantial preemphasis on the higher frequencies for the purpose of improving the record by minimizing the amount of scratch noise left after deemphasis in the reproduction. The standard recording curve and its corresponding inverse reproducing curve have a general character much nearer constant-amplitude than constant-velocity.

A constant-amplitude recording can be faithfully reproduced with a crystal pickup

having little or no equalization. It can be faithfully reproduced by a magnetic pickup with the use of a proper network with increasing attenuation at higher frequencies.

113. Tracking Error. The reproducing stylus is not operated vertically against the record but rests back at an angle. It is desirable that this angle be directly above the tangent to the groove, so that the top end of the needle is at the same distance from the center of the record as is the bottom end. Departure from this relation is called "tracking error"[1] and is usually kept to moderate proportions by placing the pickup cartridge at an angle on the end of the tone arm, or obtaining the equivalent result by a curved shape of the entire tone arm.

114. Adopted Phonograph Standards. The various standardizing groups (Audio Engineering Society, Record Industry Association of America, EIA, NARTB, etc.)
FIG. 29. Standard playback characteristic for phonograph records, showing deemphasis for noise reduction.

have adopted standard dimensions for home disk records,[2] a standard recording and playback characteristic,[3] and other standards in the recording field.

The standard value of the nominal 78-rpm speed is 78.26; this can be conveniently checked by observing a 92-bar pattern illuminated with 60-cycle flashes from a neon lamp.

The standard recording and playback curve provides substantial preemphasis for the highs in recording. Conversely the highs are deemphasized in reproduction, as shown in Fig. 29. The curve is characterized by three time constants associated, respectively, with the low-, middle-, and high-frequency regions of the audio spectrum. The dashed tangents in the drawing have a slope of 6 db per octave, and the curve at each stated value of frequency f_r departs by 3 db from the tangent line.

One of the defects to which turntable mechanisms have been subject in the past is flutter (or "wow"), which is the effect of fluctuation in the speed of rotation.[4] NARTB standards specify that the maximum instantaneous deviation from the mean speed when making a recording for broadcast-station use shall not exceed ±0.1 per cent of the mean speed.

115. Usual Practice in Home Playing of Disks. The usual practice in home reproduction is characterized by speeds of 33⅓,[5] 45, and 78 rpm, record sizes of 12, 10,

and 7 in. diameter, pickup of crystal, magnetic, or ceramic type, and the use of either a simple turntable or a record changer.

For good reproduction the reproducing stylus must be larger than the recording stylus; otherwise the reproducing stylus will rattle about in the groove. It is interesting to note that the contact areas involved are so small that the pressure is very high, probably of the order of several tons per square inch. Under this pressure the groove walls yield elastically when the record is played, but it is found that if the reproducing stylus is well polished and properly proportioned and the stylus force is held to 1 oz or less, the deformation is not permanent and the groove is not damaged even by a large number of playings.

For 78-rpm records the radius at the bottom of the groove is approximately 0.0015 in., and the radius of the needle 0.0025 to 0.0032 in. For 33⅓-rpm records the corresponding groove and needle radii are 0.0005 and 0.001 in.

The popularity of the phonograph has been enhanced by the introduction of low-priced record changers and also by the economy and performance of the rim type of drive in which a large rubber-tired pinion under the turntable furnishes motive power by driving against the turned-down edge of the turntable.

The usual phonograph combination introduces the audio signal from the pickup into the first audio stage in place of the output from the diode detector. The first audio stage is followed by the output stage, the two furnishing a total gain of about 55 db when the volume control is set at full gain. The volume control is usually a potentiometer at the input of the first audio stage and operates for either radio or phonograph use. Separate phonographs, which have been widely sold, include two audio stages and a rectifier and may also have additional tubes to provide a push-pull output stage and to use a tube inverter in place of the push-pull input transformer. In the case of a magnetic pickup, the voltage is low and a preamplifier is provided which for the present discussion is considered part of the pickup.

A limited use is being made of 16⅔ rpm in records for the home in the interest of longer playing time, and "four-speed" players accommodate these records. The usual records for the blind, sponsored by the Library of Congress, operate at 33⅓ rpm. Both these types of records operate with a needle of 0.001 in. radius. (Records for 16⅔-rpm home use differ from 16⅔-rpm automobile records, which are described in Sec. 117.)

116. Special Types of Home Reproducers. Various special disk-playing methods have been devised, such as the modulation of a light beam by a mirror attached to the reproducing needle. Another special arrangement[1] produces a.m. of a 2.5-Mc oscillator by movement of a vane attached to the needle. This design has low mechanical impedance and requires a stylus force of only ½ oz (14 g), so that it produces very little wear of the records. Other designs in which the needle produces f.m. of an oscillator have been described.[2]

117. Phonograph for Automobiles. A phonograph for installation in automobiles has been introduced.[3] By the use of a needle radius of ¼ mil (0.00025 in.), it is possible to space the grooves closer (about 550 per in.) and thus with a 16⅔-rpm speed and a 7-in. record diameter obtain 45 min of music or 1 hr of speech per side. A stylus force of 2½ g is used. The signal and noise are each about 6 db below the values for a conventional 33⅓-rpm record, so that the signal-to-noise ratio is approximately the same.

Vibration and road shocks are controlled by (1) a rubber shock-mount system, (2) a uniform weight distribution, and (3) counterbalancing the tone arm about both axes. In this way the difficulties of wow and change of stylus force are obviated.

[3] Goldmark, P. C., A Phonograph System for the Automobile, *IRE Convention Record*, **4**, Part 7, pp. 159–165, 1956.

Constant turntable velocity is obtained by an induction motor driven from a 60-cycle vibrator.

118. Wireless Phonograph Attachments. One of the standard forms of phonograph equipment is a wireless attachment or phonograph oscillator which produces an a-m wave in the broadcast band for reception by the ordinary broadcast receiver. Many of these designs utilize the l-f end of the broadcast band, being adjustable, for example, from 530 to 730 kc. Others are adjustable similarly at the upper end of the broadcast band, *e.g.*, anywhere from 1,500 to 1,800 kc. These equipments usually consist of a one-tube modulator and a one-tube rectifier. The only external connection is to a 110-volt outlet. This must ordinarily be a.c. owing to the motor power requirement. At the time of installation the frequency of the oscillator is set at an appropriate point well removed from any local broadcast stations.

These equipments are permitted by the FCC to operate without a transmitting license on the condition that the field strength must not exceed 15 μv per m at a distance equal to the wavelength divided by 2π.

119. Frequency Records for Testing. Various firms have made frequency records which are of much value in experimental development, as well as in high-grade maintenance work. Some of these are listed in Table 11.

Table 11. Phonograph Test Records

Company	33⅓ rpm	45 rpm	Type of characteristic
Columbia	No. TL-1	None	Approx RIAA*
RCA Victor	No. 12-5-49	No. 12-5-51	Accurate RIAA*

* RIAA = Record Industry Association of America.

120. Dynamic Noise Suppression. A circuit known as a "dynamic noise suppressor" has been introduced by Scott to improve the reproduction of noisy phonograph records[1] on the following basis. When music is at a low level, the lowest and highest pitches are inaudible. There is therefore no harm done to the quality of reproduction if the system introduces high attenuation for these components. Under these circumstances noise present in the same frequency regions is removed, and the reproduction may sound quieter. This noise suppressor is, therefore, a device which controls the frequency band in the reproduction and varies it automatically in accordance with the volume and frequency characteristics of the music. The frequency band is widened during loud passages and contracted during weak passages, the action being independent at the bass and treble ends of the audio range.

The noise to be reduced consists of scratch in the treble region and motor rumble in the bass region. These noise levels, except for a small portion of the time, may be more intense than the musical components existing in the same frequency regions. It is possible to control each end of the spectrum by means of signals present in a region nearer to the center of the audio range. Control in this way resides effectively in the signal rather than in the noise. With music this is possible, since high harmonics exist only when there are fundamentals of somewhat lower frequency which can be used to operate the control. Similarly at the bass end, whenever deep fundamentals are present they are accompanied by harmonics of appreciable amplitude which can be used to control the cutoff.

A model of this suppressor designed for use in broadcast stations has 13 tubes. It provides 20 db of scratch reduction and about 15 db of rumble reduction. Models suitable for home use add two or three tubes to the normal receiver complement.

MAGNETIC RECORDING[1]

121. Home Recorders. There is an increasing interest in the home recording of favorite radio programs as well as the voices of children, members of the family, etc., and in the reproduction of musical pieces from purchased prepared magnetic tapes. Recorder-reproducers for such home use are offered in many models.[2] These utilize magnetic tape of ¼-in. width. The most frequently used speeds are 7½ and 3¾ in. per sec, with some use of 1⅞ and 15 in. per sec and other speeds. The total film thickness may typically be approximately 0.002 in.

122. Ultrasonic Bias. The high quality of sound reproduction afforded by magnetic tape is due in part to the use of an ultrasonic "bias" of 30 to 70 kc which is applied to the tape along with the audio signal. This type of operation substantially improves the linearity and therefore reduces distortion.[3]

VOLUME EXPANSION AND COMPRESSION

It is possible in an amplifier to vary the gain in such a way that the greater the input, the greater the gain. Such an action is called "volume expansion" because the range of volume applied to the amplifier is increased or expanded. Conversely, the gain may be varied in the opposite direction to produce volume compression.[4]

123. Use in Point-to-point Radiotelephony. Volume compression and expansion are a well-established method of improving the signal-to-noise ratio in point-to-point radiotelephone practice. In this field the term "compandor" is used to designate the compressor and expander equipment at the two ends of the radio link. The compressing and expanding operations are performed at audio frequency and require the use of suitable time constants and other refinements.[5]

124. Compression in Broadcasting and in Phonograph Recording. In broadcast practice symphonic music is compressed by strengthening the weak passages with a manual volume control and reducing the loud passages by either manual or automatic means. Such compression is considered necessary to keep up the average percentage of modulation of the station to deliver a usable signal in the outer parts of the service area, and at the same time avoid overmodulation on the strong passages. In recording phonograph records, compression is similarly used to make the music conform to the limitations of the medium. Both the radio and record reproduction are, of course, normally carried out without any compensating expansion.

There is a question as to whether the listener under typical conditions desires the reproduction of a classical program at the full volume range. To have such a true rendition of the music, the listener must be in a quiet place so that he can hear the pianissimo passages without difficulty, and he must also be in such a place that the fortissimo passages will not be objectionable to other persons in the vicinity.

In some situations, *e.g.*, in receivers operating in automobiles (or receivers for speech in locomotive cabs), it may be desirable to introduce compression rather than expan-

sion so that the volume may be held near a level sufficient to be heard easily over the noise and yet not rise to objectionable loudness during high-modulation periods.

125. General Methods. Equipment with an expansion feature has been offered to the public in a few models during past years. These have been intended especially for phonograph reproduction, where the operation is facilitated by the fact that the compression is more systematic than with broadcast radio programs.

One de luxe method of obtaining compression and expansion in a system is to have a separate pilot control channel, which transmits a signal at all times representing the amount of compression at the transmitter and controlling the compensating expansion at the receiver.[1]

In the absence of a pilot control channel, expanders for broadcast and phonograph use must have different time constants for their operate and release actions. In particular, the time constant for taking hold must be quite short, such as 0.001 sec. The release time must be much greater, such as ½ to 1 sec. The amount of expansion can reasonably be about 10 db at the loudest passages.[2]

126. Expansion by Tube Characteristics. One method of obtaining expansion is by control of the grid bias of an amplifying tube.[3] Such control is usually made progressive, or forward acting; *i.e.*, signal is rectified and the resulting bias used to vary the gain of a tube farther along in the system. Either diode tubes or germanium crystals, such as the 1N34, can be used for the development of bias for expansion.

An alternative method of using a tube for expansion is to connect the plate circuit of a triode so that its resistance is part of a gain-control potentiometer in the amplifier. The 6C5G triode has been used in series with a fixed 50,000-ohm resistor for this type of operation.

Two other available methods of using tubes for volume expansion are (1) connecting the plate circuit of a controlled tube in parallel with the plate circuit of the regular tube, the control arrangements being such that at low levels the shunt loss is greater than at high levels, and (2) employing a pentode or heptode with the audio signal on one grid and the control bias on another grid.

127. Expansion by Nonlinear Resistance. The wide variation of resistance of lamp filaments with current or voltage has been used to furnish volume expansion. However, thermistors[4] (resistors whose value varies with temperature) are more useful for this purpose. In a typical case the resistance is 50,000 ohms at a very low electrical level but declines to only 800 ohms when dissipating 100 mw. These thermistors can be used in shunt across the circuit to produce compression or in series in the circuit to produce expansion. By arrangement in a bridge manner, d.c. can be passed through them to produce further control of the amount of expansion or compression, the d.c. being developed from the signal itself.[5]

A striking application and extension of compression and expansion technique was demonstrated in 1941 by Harvey Fletcher and others of the Bell Telephone Laboratories.[6] This included the feature of manual control of the expansion by a musical conductor, who thereby was effectively given an orchestra of a thousand pieces available at the turn of a knob. This possibility of "enhancement" of the original volume range affords very impressive musical effects. A three-dimensional feature was also shown by the use of three channels with speakers at the two sides and center of the stage. The volume range

of the "stereophonic" film was 50 db, which was increased to 80 db by the use of 30-db normal compression and expansion. The enhancement was obtained by further expansion when desired. This system included three pilot channels, one for the control of the volume of each of the loud-speakers on the stage, the control frequencies being 1,260, 3,780, and 6,300 cps. The single film included three sound tracks for the three loud-speakers and a fourth track on which the three pilot frequencies were recorded. In the reproduction the three pilot frequencies were separated from each other by audio filters and each then used to control the volume of its assigned channel. Optical-photographic recording was used for the four tracks on the film.

In this demonstration the thermistor type of element was used for both the compression in making the film and the expansion in reproduction.

A-C–D-C AND THREE-WAY RECEIVERS

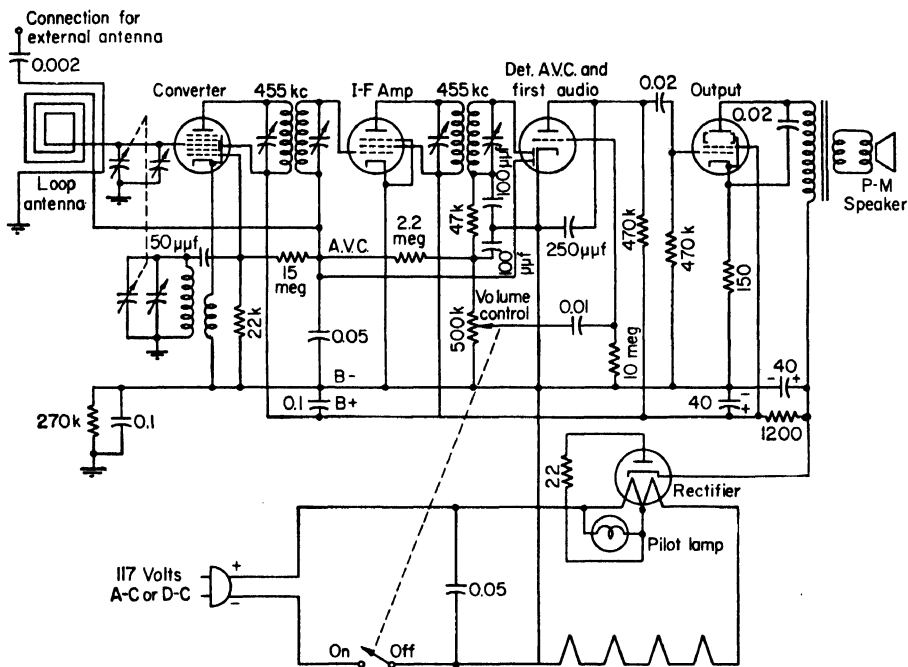
The a-c–d-c type of power supply is popular because of (1) the economy of not requiring a power transformer and (2) the adaptability to either a-c or d-c power supplies.


FIG. 30. Typical a-c–d-c receiver circuit.

128. Essential A-c–D-c Features. In the a-c–d-c power system the heaters of the tubes are operated in a series circuit connected across the line, and the plate circuit is operated as an additional load circuit with a half-wave rectifier in series. Figure 30 gives a typical circuit of an a-c–d-c receiver, and it may be noted that the power plug is marked with + and − indications. This polarity must be observed when the set is operated from a d-c outlet. The set is inoperative when plugged into a d-c outlet with the opposite polarity because the tubes have no plate supply. When the set is operated on a.c., heater current flows throughout the a-c cycle, but plate current flows only when the a-c wave has the proper polarity and is near its peak value. The 40-μf capacitor connected from the cathode of the 35Z5GT rectifier to B− maintains most of its charge during the power-frequency cycle so that it is only at positive peaks of the

a-c wave that the rectifier passes current and this capacitor assumes its maximum charge. The action is similar to peak detection.

On account of this pulselike flow of plate current from the a-c line, an a-c–d-c receiver may not operate satisfactorily when an external series resistor is used to adapt a 110-volt set to a higher a-c socket voltage, such as 220 or 250 volts. Separate resistors for the A and B supplies, or other special arrangements, may be necessary.[1]

Selenium rectifiers are now available as a substitute for the tube type and offer the advantages of (1) greater compactness, (2) less production of heat, (3) longer life, and (4) in the usual three-way receiver (operating on a-c, d-c, or battery power) immediate starting of reception after the receiver is turned on.

Capacitor-input filters are always used in a-c–d-c receivers. If the first capacitor in a set with a tube rectifier materially exceeds 40 μf, the set will be subject to failure whenever the user turns it off and then quickly turns it on again. Under these conditions the filter capacitor will quickly discharge, the rectifier cathode will remain hot for the short time involved, and the result will be that, when the set is turned on again, the tube current limit of 500 ma may be greatly exceeded by the rush of current into the capacitor, ruining the rectifier tube and possibly other parts of the receiver. The design in Fig. 30 includes a 22-ohm resistor in series with the rectifier plate as a protection against this effect. This resistor often has a fuselike type of construction so that, if overloaded owing to a short circuit anywhere on the plate-supply system, it will burn out without damaging the rectifier tube. A study of these matters made by Tung-Sol led to the recommendation of the resistance values shown in Table 12 for protection of the rectifier tube.

Servicemen have been advised to install a 50-ohm resistor in all a-c–d-c sets not already equipped for the protection of the power rectifier. This gives sufficient protection unless a very large first filter capacitor is used.

Higher plate voltage in an a-c–d-c set when operating on a-c supply can be obtained by the use of a voltage-doubler rectifier circuit.

Since a-c–d-c sets are usually housed in small cabinets of limited acoustic properties, various suggestions have been made for improving the audio quality and in particular for improving the apparent amount of bass in the sound. One arrangement advanced by F. H. Shepard, Jr., is to introduce a small amount of distortion at all volume levels in the audio amplifier, there being about 5 per cent of third harmonic always present and a small amount of fifth harmonic. In this way the output-input characteristic is changed from a straight line into a slightly S-shaped curve. The resulting distortion is stated to give the listener the impression that the set has fair output at quite low audio frequencies. This feature was demonstrated to the Radio Club of America in September, 1941, and has been described briefly in the literature.[2]

129. Three-way Receivers. The addition of circuits for battery operation to an a-c–d-c design produces a convenient form of receiver, usually called a *three-way* type. Various arrangements of switches are suitable for adapting the receiver to either the socket-power outlet or to the batteries carried internally. In one method battery operation is obtained by "plugging in" the normal power cord at a socket on the receiver, this action serving to operate mechanically a switch which connects the A and B batteries into the circuit—*i.e.*, for battery operation no electrical contacts

[1] This condition has been encountered in England and is discussed by F. Langford-Smith in "Radiotron Designer's Handbook," RCA, Harrison, N.J., 1952, pp. 1264–1266.

[2] Improved Bass for Small Radios, *Electronics*, July, 1945, p. 224.

are made to the pins of the power cord, but these pins press against certain movable parts which operate the battery switching.

Designs of receivers for battery operation usually necessitate a careful consideration of the electrical and mechanical characteristics of available battery types. Substantial improvement in battery performance and/or life for a given physical size has been made during the years. An American Standard is available[1] giving dimensions, tests, performance, and terminal arrangements.

MINIATURIZATION

130. Methods and Results.[2] Reduced size offers advantages for three-way portable receivers as well as for virtually all other classes of electronic equipment. Means for obtaining reduced size include the use of (1) transistors instead of tubes, (2) miniaturized capacitors, coils, resistors, speakers,[3] and other components, and (3) printed-circuit wiring and other special assembly methods. If these various techniques are intensively applied, a point is likely to be reached where inadequate heat dissipation and consequent excessive temperatures threaten to damage the circuit parts.[4] For dissipations above about 1 watt per sq in. of exposed surface, simple radiation and free convection do not afford sufficient cooling.[5]

A subminiaturized design of an air-borne receiver tunable over the range from 190 to 550 kc, in which tubes were retained but various other special components were incorporated, was made by the National Bureau of Standards.[6] The size was reduced to 55 cu in. (corresponding to a cube 3.8 in. on a side), in which a 12-tube circuit was contained having a sensitivity in the region of 1 to 4 μv, image and i-f rejections exceeding 80 db, and ample output for headphone operation. The i.f. was 135 kc.

A *printed circuit* consists typically of a paper-base phenolic board having on one side copper foil of suitable arrangement to constitute the various connections and on the other side the circuit components, such as resistors, coils, and capacitors, with holes through the board for the leads from the components. With this construction a single dip of the copper-foil side into a solder bath makes all connections to the components.[7] This manner of making the circuit connections has the advantages of compactness, reliability, and adaptability to economical manufacture. The term printed circuit is also applied to ceramic assemblies such as the capacitor and resistors constituting an interstage coupling.[8]

Additional data regarding miniaturization are given in connection with special manufacturing methods in Sec. 203.

Miniaturized i-f amplifiers for radar service, using subminiature tubes, can be designed with a volume, e.g., of 5.25 cu in. for a six-tube unit. With special attention to the various components, ambient temperatures as high as 85 to 100°C, producing

internal temperatures up to 175 to 200°C, can be accommodated. Grooving or fins for cooling will ordinarily lower the internal temperature by 10 to 20°C at the cost of additional equipment volume.[1]

REFLEX OPERATION

131. Reflex Principle. Although little used in the United States, the reflex principle is one of the standard methods available to the radio design engineer. A reflex circuit has been defined in the IRE Standards as one through which a signal wave passes both before and after a change of frequency. Since such a circuit has currents of two different frequencies, it has two inputs and two outputs, and filtering is necessary to separate the two outputs.

The field of usefulness is where power levels are low and the number of tubes is restricted by economic or technical factors. European broadcast receivers have often included a reflexed tube serving as both an i-f and a-f amplifier. Both pentodes and converter tubes have been used in this way. In the case of the converter tubes, the mixing feature is not required, but the two input grids offer convenient points for applying the two frequencies. Another possibility is to amplify both the r-f signal as received and the i-f signal, but such designs are likely to have poor performance for radio frequencies which are harmonics of the i.f.

A tube operating in a reflex circuit is subjected to the sum of the peak voltages and currents at both operating frequencies, so that the power levels must not be too high. If care in this regard is not taken, distortion will occur; in particular, tubes handling i-f and a-f signals may give poor audio quality. Besides keeping the power levels low, points worth some consideration are increasing the plate-supply voltage within the rating of the tube, or choosing a larger tube. The power limitation will probably make it undesirable to apply a.v.c. to a reflexed stage; however, if the stage handles i-f and a-f signals and a.v.c. is applied, the control of the a-f gain constitutes forward-acting a.v.c., so that a very flat a-v-c curve should be obtained.

Wide use of the reflex principle has been made in Australia, particularly in receivers having three tubes and a power rectifier, the three tubes serving as (1) converter, (2) reflexed i-f and a-f amplifier and diode detector, and (3) output audio stage.[2]

F-M RECEIVERS

Frequency modulation is extensively used for such purposes as police service around 35 Mc, broadcasting around 100 Mc, automobile and railroad telephone around 155 Mc, and the sound channels of television.[3]

132. Modulation Index. The ratio of maximum frequency swing to one side divided by the highest frequency component in the modulating signal is called the *modulation index*. In police service the deviation is usually 15 kc to each side, and the highest a.f. transmitted is 3 kc, giving a modulation index of 5. For present-day broadcast practice the corresponding figures are 75 and 15 kc, again giving a modulation index of 5. For the sound channel of television broadcasts the maximum deviation is 25 kc.

On certain segments of the amateur bands the FCC has authorized the use of "narrow-band" f.m. which is subject to the requirement that "the peak deviation is limited to a value equal to or less than the maximum modulation frequency." This corresponds to a modulation index of unity or less.[4]

[4] Miller, E. C., Frequency Discriminator for Narrow-band F-M, *Electronics*, **26**, 128, February, 1953.

133. Transmitter Specifications Affecting F-m Broadcast Receivers. For f-m broadcasting the FCC "Standards of Good Engineering Practice" establishes 88 to 108 Mc as the f-m broadcast band, divided into 100 channels of 200 kc each.

The FCC adopted in 1947 a rule that the normal spacing between stations in a given locality will be 800 kc to avoid interference difficulties found in tests in Syracuse and also to permit the construction of economical receivers having a limited number of tuned circuits for selectivity.

Modulation of 100 per cent in f-m practice does not have a unique definition such as it has in a-m practice. The FCC has standardized this for f-m broadcasting as ± 75 kc. On this basis 30 per cent modulation, which is often used for testing, is a deviation of ± 22.5 kc.

In FCC "Standards of Good Engineering Practice," the signal intensities stated as necessary for satisfactory reception are 1,000 μv per m for city, business, or factory sections and 50 μv per m for rural sections. Objectionable interference is considered to exist for stations on the same frequency if the undesired field strength exceeds $\frac{1}{10}$ of the desired. For stations separated by 200 kc, the corresponding figure is $\frac{1}{2}$. Stations in a given area will normally not be assigned frequencies differing by 10.7 Mc, since this is the usual i.f. for f-m receivers.

The audio characteristic of f-m broadcast transmitters must extend from 50 to 15,000 cycles, with preemphasis on the upper audio frequencies in accordance with Sec. 134. The maximum audio harmonic distortion is specified as 3.5 per cent total harmonics for any fundamental frequency between 50 and 100 cycles, 2.5 per cent for any fundamental from 100 to 7,500 cycles, and 3.0 per cent for any fundamental from 7,500 to 15,000 cycles. The f-m noise level in the transmitter output must be at least 60 db below full modulation; *i.e.*, the noise deviation must not exceed 75,000/1,000, or 75 cycles. The a-m noise level must be at least 50 db down, which for a 1-kw station means less than 0.01 watt.

134. Preemphasis of Upper Audio Frequencies. Since most of the energy in speech and music is contained in the lower audio frequencies, it is possible to reduce the noise in a system by reenforcing the medium and high audio frequencies at the transmitter and then correspondingly attenuating these regions at the receiver. In this way the modulation of the transmitter for these frequencies is increased, requiring a slight reduction of modulation for the lower frequencies, while a large reduction of noise is obtained by means of the compensating attenuation at the receiver. For this reason the FCC specifies that "preemphasis shall be employed in accordance with the impedance-frequency characteristic of a series inductance-resistance circuit having a time constant of 75 μsec." The significance of this statement, which specifies preemphasis in microseconds, can be visualized by assuming that the inductance and resistance are connected in series in the plate circuit of a constant-current audio source, such as a pentode amplifier. At the lowest frequencies the impedance of the inductance will be negligible, so that the plate voltage is merely IR. At the high frequencies the reactance of the coil will greatly exceed the value of the fixed resistor, so that the plate voltage is almost equal to IX_L. The plate voltage, therefore, will gradually increase for a given current as higher audio frequencies are applied. The 75-μsec provision merely means that the ratio L/R must be 75×10^{-6}; *i.e.*, there must be 75 μh per ohm of resistance or the equivalent relationship of 13.3 ohms of resistance per millihenry of inductance.

The extent to which the upper frequencies are reinforced by a circuit of 75 μsec time constant is shown by the solid curve in Fig. 31. Since some tolerance is necessary with actual equipment, the FCC requires each station not to have greater preemphasis than this and allows each to have less preemphasis down to the dashed line in the figure. The following formula can be used for computing preemphasis at any frequency:

$$(\text{db})_p = 20 \log_{10} \sqrt{1 + 0.222 \times 10^{-6} f^2}$$

where f is in cycles. This formula, like the solid curve in Fig. 31, gives the preemphasis at any frequency in comparison with the lowest audio frequencies.

The same amount of preemphasis is used in the sound channels of television broadcast stations.

At the receiver it is necessary to introduce an h-f loss, *i.e.*, a deemphasis, to restore the audio frequencies to their proper balance and to realize the advantage in noise reduction. It is usually the practice in receiver design to observe the amount of loss for the upper frequencies present due to the natural characteristics of various elements and then to add a shunt capacitor at one point of such value as to increase the loss to the necessary amount. As a matter of theoretical interest, it may be noticed that, should all the necessary deemphasis loss be inserted at one point, an *RC* combination
FIG. 31. Preemphasis of upper audio frequencies in f-m broadcasting and in sound channel of television system.

of 75 μsec would be required, such as furnished by 50,000 ohms in parallel with 1,500 μμf or by 25,000 ohms in parallel with 0.003 μf.

A different standard preemphasis is used in f-m mobile services. In this case a uniform rate of 6 db per octave is employed.

135. EIA Standards for F-m Receivers. The EIA has standardized upon a balanced 300-ohm transmission line for the input connection of f-m broadcast receivers. A parallel-wire construction with a continuous low-loss plastic separator is available for this service.

The standard i.f. is 10.7 Mc. This value slightly exceeds half of the 20-Mc total width of the f-m band, which is 88 to 108 Mc, so that no f-m station will lie on the image when another is being received. The possibility, of course, still remains that image interference may be encountered from other services outside the 88- to 108-Mc band.

Under the EIA standards and also the requirements of FCC, f-m broadcast receivers are limited in the allowable amount of oscillator interference, as discussed in Sec. 20. In the case of a receiver with a triode r-f stage and a triode modulator, a reduction of radiation can be obtained by applying the oscillator injection on the cathode and the r-f signal on the control grid of the modulator and using a neutralizing circuit to

annul the oscillator voltage on the control grid of the modulator. Bridge arrangements can also be used for controlling radiation.[1]

Tests to determine the various properties of f-m broadcast receivers are described in Sec. 22. F-m receivers for mobile services are tested as described in Sec. 167.

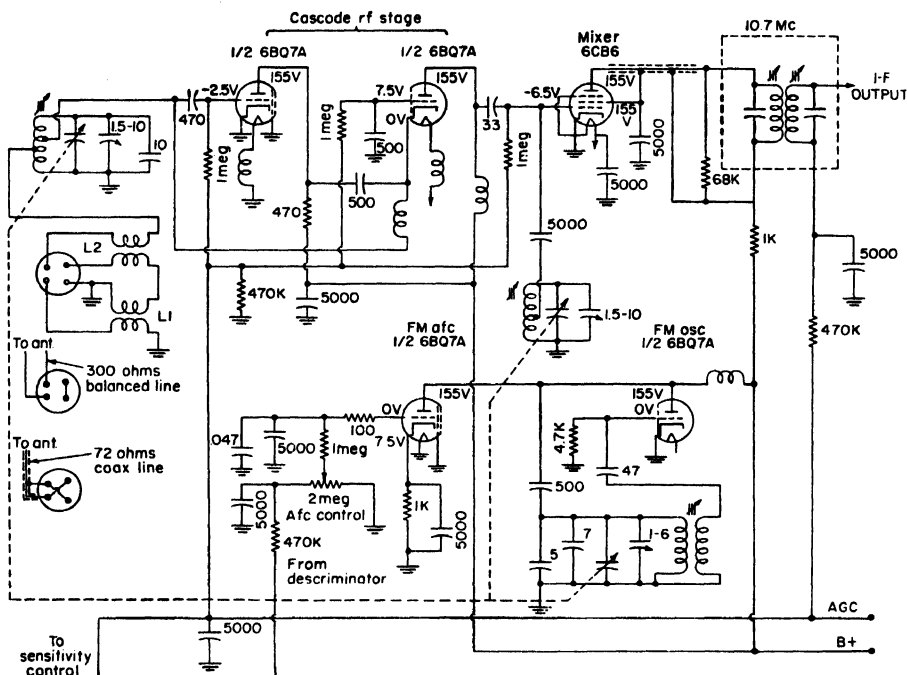
136. Application of Negative Feedback to Oscillator of F-m Set. If the output audio voltage delivered by an f-m receiver is used to produce f.m. of the local heterodyne oscillator of the receiver with such a direction as to reduce the frequency difference between the oscillator and the incoming signal, a form of negative feedback is obtained[2] in which the frequency swing of the i-f signal is reduced. In this way distor-


FIG. 32. Front end of high-grade f-m tuner. (*Courtesy of Fisher Radio Corp.*)

tion originating in the receiver can be greatly reduced, so that the method is of special interest in connection with multiplex f-m systems, such as used in point-to-point practice.[3]

137. F-m Broadcast Receivers. Although numerous techniques are available for the design of receivers for f-m broadcasting, experience has shown that acceptable results at the lowest cost are obtained with a rather standardized group of features. These include the superheterodyne circuit tuned by a capacitor gang with the oscillator frequency higher than the signal. An r-f stage is generally used, and the more selective sets have a three-gang capacitor for tuning the antenna circuit, the interstage coupling, and the oscillator. A less selective design is also made in which a two-gang capacitor tunes the interstage coupling and the oscillator; *i.e.*, the antenna circuit has a fixed broad tuning for the entire band from 88 to 108 Mc.

[3] Clavier, A. G., and G. Phelizon, Paris-Montmorency 3000-Mc F-m Link, *Elec. Commun.*, June, 1947, p. 159.

Low-noise types of r-f stages, especially the cascode circuit,[1] are suitable for high-grade f-m tuners, such as offered for high-fidelity receivers. An example of this in a manufactured tuner is shown in Fig. 32. The circuit is seen to include also automatic frequency control (a.f.c.). Another feature is the provision for either a 300-ohm balanced or a 72-ohm coaxial transmission line, bifilar coils L_1 and L_2 serving as balun for the 300-ohm case and as impedance matcher for the 72-ohm case.

A minor disadvantage of capacitive station tuning is that the common coupling in the capacitor rotor shaft in a three-gang design limits the gain of the r-f stage to about 20 db. The capacitive design is, however, generally used for other reasons.

138. Design Points on F-m Broadcast Receivers. The 100-Mc f-m band is high enough for the grid losses of tubes to be important. Tubes suitable for use as r-f amplifiers include the 6AK5, 6AC5, 6SC7, and 6BA6 pentodes and the 6BQ7A and 12AT7 double triodes. For converter, suitable types are the 7F8 and 12AT7 double triodes, the 6CB6 and 6AK5 pentodes, and the 6SB7Y and 6BE6 heptodes. As separate oscillator, if one is used, the 6C4 triode and the 7F8 are suitable.

The i-f and detector design may consist of two i-f stages, followed by a grid-current limiter and a discriminator. Such a limiter, however, does not reject a.m. of fairly high frequency, such as the 400- or 600-kc undulation due to interference from the second or third channel away in frequency allocation; in fact, these limiters increase such interference. This drawback is avoided and one tube saved by using only one i-f stage, followed by a driver stage and a ratio detector.

For the reception of 100-Mc f-m broadcasts in automobiles, an experimental receiver has been used with limiter and f-m detector of substantially greater band widths than in a home receiver. This design was reported to afford good reception despite multipath propagation conditions.[2]

139. Tuning Indicators. High-grade f-m receivers should be provided with a tuning indicator. Medium-price sets can be tuned fairly well by the user without a tuning indicator if (1) the selectivity curve falls off about 6 db at ± 75 kc, (2) no limiters are used, (3) a ratio detector is used, and (4) only a limited amount of a-v-c action is provided.

A simple tuning-indicator circuit for receivers having limiters is one which develops a control voltage from the grid current of a limiter stage.

The 6AL7GT electron-ray tube with three deflecting plates is specially suitable for f-m receivers and is discussed in Sec. 91.

140. F-m Detectors. The phase-variation, discriminator, or "coupled-circuit" type of f-m detector is similar to the discriminator of an a-f-c system described in Sec. 97.[3] While the carrier frequency is not being deviated, this detector rejects a.m. by virtue of the equal and opposite rectified voltages in its output circuit. However, when the frequency is at some deviated value, one rectified voltage exceeds the other, and it can be seen that an increase of level due to a.m. will increase both rectified voltages and therefore their difference. For example, if the voltages were -5 and $+6$, with no a.m., and were doubled by the a.m. to -10 and $+12$, the differential output would be increased from 1 to 2 volts.

The choice of type of f-m detector for a sound broadcast receiver (for 88 to 108 Mc) is more restricted than for the sound channel of a television receiver for the reasons that (1) normally higher audio fidelity is desired, and (2) the variation of the 10.7-Mc carrier when tuning to a station must be accommodated in distinction to the fixed 4.5-Mc carrier in the intercarrier television receiver.

141. Ratio Detectors. Detectors[4] having the property of being insensitive to a.m., while the carrier is deviated as well as when it is not, have been developed. Of special

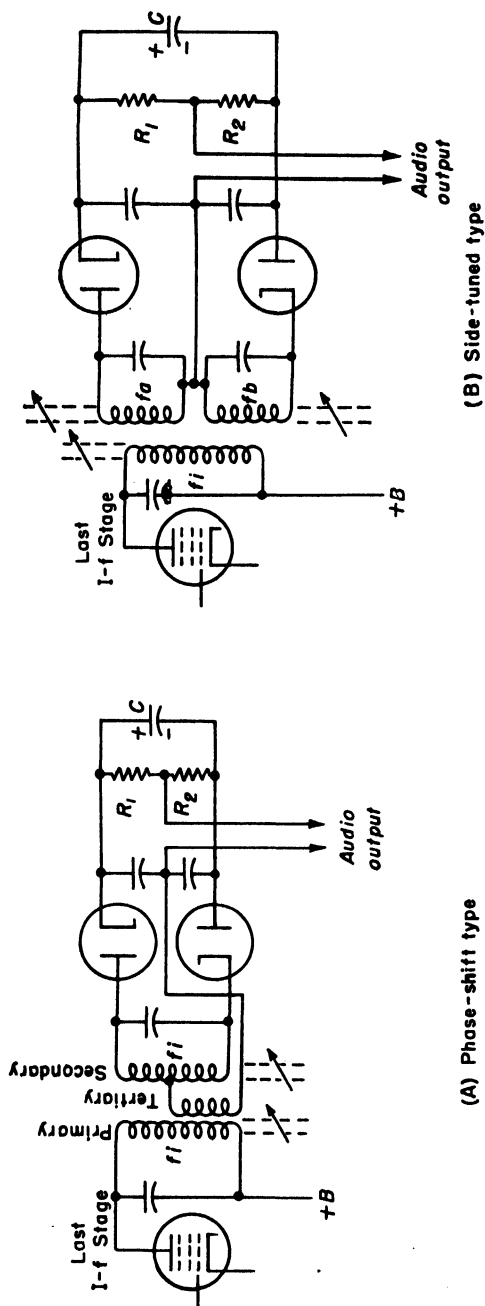

FIG. 33. Essential parts of the two general types of ratio detectors.

interest is the ratio detector,[1] which has this property and obtains its name because of its sensitiveness to the ratio of the two voltages developed from the applied signal, rather than to their difference. Since the ratio between the two voltages is the same at any level, an ideal ratio detector does not respond to a.m. at any frequency deviation.

There are two general types of ratio detectors, the essential parts of which are shown in Fig. 33. The phase-shift type is the more widely used. Fundamentally, the two types differ only in the use of a different i-f coil structure between the last i-f stage and the diodes. In common with discriminators, ratio detectors make use of phase shift or of side tuning to develop the necessary frequency-sensitive i-f voltages. The tuning of the side circuits in the side-tuned type is shown in Fig. 33*B* by the notation f_a and f_b to indicate the resonant frequencies of the two side-tuned circuits, one above and one below the center value of the i.f., f_i.

The ratio detector differs from the discriminator in the use of a large capacitor C which maintains a constant voltage during all a-f variations. The time constant of C, R_1, and R_2 has a typical value of $\frac{1}{10}$ sec. For example, C may be 8 μf and R_1 and R_2 may be 6,800 ohms each.

Considerable care is necessary in the design of the transformers and detail circuits of ratio detectors to secure good results. Accurate balance and other refinements are necessary.

A reasonable sensitivity requirement for a driver i-f stage and ratio detector operating at an i.f. of 10.7 Mc is that a signal level of 0.1 volt rms on the driver

[1] Seeley, S. W., and Jack Avins, The Ratio Detector, *RCA Rev.*, June, 1947, p. 201. This paper is also partly given under title Ratio Detector for FM Signals, *Tele-Tech*, July, 1947, p. 46. Hayes, Albert T., Jr., Improved Type of Ratio Detector, *Tele-Tech*, November, 1947, p. 41.

grid with a 22.5-kc (30 per cent) deviation should produce an audio output of about 0.2 volt rms.

The characteristics of the f-m detector in a receiver have an important effect on the apparent tuning action. For example, if the over-all i-f band width at 6 db down is between 150 and 200 kc, the tuning action will be good if the separation of the detector peaks is 300 to 400 kc (± 150 to ± 200); otherwise a noticeable false response may occur on each side of the correct tuning point. The separation of the detector peaks can be observed by using a battery and potentiometer to hold across C a voltage corresponding to the signal strength of interest and then applying in succession various unmodulated i-f signals over a frequency range extending beyond the peaks in each direction.

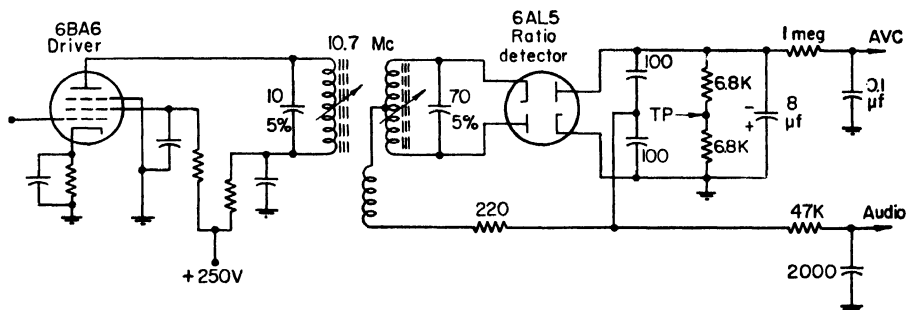
Theoretical and experimental work[1] confirms that the rejection of a.m. by a ratio detector is produced in a different way from ordinary limiting, such as accomplished


FIG. 34. Practical arrangement of phase-shift ratio detector for 10.7-Mc intermediate frequency. For alignment connect high side of VTVM to audio output and low side to test point marked TP.

by conventional grid-circuit limiters which remove a.m. from the carrier wave. An oscilloscope may show some a.m. on the carrier wave to be removed by a ratio detector; however, this action is incidental and unrelated to the a-m rejection properties. Ratio detectors can be designed to achieve complete a-m rejection when the apparent limiting action is very small. While a diode dynamic limiter (see Sec. 142) has best limiting action with the highest diode conductance, practical ratio-detector circuits usually add resistance in series with each diode to obtain optimum a-m rejection.

Germanium crystals can be used in place of vacuum diodes in ratio detectors, but may require added series resistance to reduce the forward conductance. They also have the limitation that the backward conductance may increase at high signal levels and thereby impair the detector performance.

The grid-to-plate voltage gain of the driver can be substantial. A reasonable maximum figure can be obtained by subtracting 8 or 10 db from the result given by the following expression:

$$20 \log_{10} \left(2 \times \frac{\text{reactance of grid-plate capacitance}}{\text{resistive component of grid impedance}} \right)$$

This formula gives the maximum gain, measured at resonance, for a ratio-detector driver that will just start to oscillate when it is detuned during alignment to the point where maximum feedback occurs. For example, the maximum safe gain at 10.7 Mc for a 6BA6 tube ($C_{gp} = 0.0035\ \mu\mu\text{f}$) in a circuit having an effective grid resistance of 36,800 ohms (Q of 72, C of 30 $\mu\mu$f) would be 46.8 db. The driver gain in this case

[1] Loughlin, B. D., The Theory of Amplitude Modulation Rejection in the Ratio Detector, *Proc. IRE*, **40**, 289, March, 1952.

should not, therefore, be allowed to exceed 37 to 39 db. Note that the value of the resistive component of the resonant impedance in the driver external grid circuit when the primary is well detuned is to be used as the denominator in the formula.

The circuit of a ratio detector with values of the elements is given in Fig. 34.

142. Dynamic Limiters. The grid-bias type of limiter cannot be given a short enough time constant to follow the envelope and eliminate a.m. of high frequency, such as the 400 kc encountered in second channel interference. This difficulty can be avoided by the use of a "dynamic limiter" which utilizes one or two diodes that respond instantly to amplitude variations and limit them. Like a ratio detector, it
FIG. 35. Dynamic limiter for f-m receiver.

has an *RC* circuit which holds its characteristics constant with regard to a-f variation but permits slow change to adjust the signal level. The dynamic-characteristic curves (Fig. 35) are therefore almost flat, while the static characteristic is a linear output-input relation. Used with a phase-variation discriminator (which is not a ratio detector), the dynamic limiter gives the receiver the tuning action shown in Fig. 35. The side responses are fairly weak, being about 17 db down. There is relatively little interstation noise, a property similar to that of a ratio detector.

Practical further utilization of the dynamic limiter can be made by the substitution of a germanium crystal in place of the vacuum diode. By the use of two diodes or crystals with opposite polarity, both halves of the modulation envelope can be controlled. Also the dynamic limiter can be used with a ratio detector with very good performance and a relaxation of the requirements on each. It is worth noting that the use of a dynamic limiter with a ratio detector affords the best performance now obtainable in an f-m receiver.

HIGH-FIDELITY RECEIVERS

Most radio receivers produce a quality of sound which leaves a good deal to be desired in comparison with the original music or speech. The defects include restriction of the frequency and amplitude ranges and the introduction of hum, noise, and extraneous harmonic and intermodulation frequencies. Receivers which substantially surpass the average set in the quality of reproduction are called "high-fidelity receivers."[1]

143. Characteristics of Ear and of Music, Speech, and Sound Effects. The characteristics of the ear[2] for persons twenty years of age include a frequency range from 20 to 16,000 cps with the greatest sensitivity over the portion from 1,000 to 5,000 cps. In this central range an average twenty-year-old listener can hear sounds over the large intensity range of 105 db at 1,000, 110 db at 2,500, and 105 db at 5,000 cps. For higher or lower frequencies, the intensity range of the ear greatly declines as this central frequency region is departed from. This intensity range is, however, not fully utilizable in listening to the average receiver operating with a loud-speaker because of interfering room noise which is always present and masks faint sounds that would otherwise be heard. The sensitivity of the ear for the higher frequencies declines with increasing age, especially for men so that at age fifty-five the sensitivity at 7,040 cycles is −24 db for men and −19.7 db for women.[3]

Although frequencies as low as 20 cps and components as high as 15,000 cps exist in music, an analysis by Fletcher[4] leads to the conclusion that under practical circumstances substantially complete fidelity for symphonic music is obtained with a volume range of 65 db and a frequency range from 60 to 8,000 cps. For speech the corresponding figures are 40 db and 100 to 7,000 cps.

The single-channel character of the normal radio system produces what may be called a "monaural" type of operation, so that the binaural or "stereoscopic" feature made possible by the two ears of the listener is not used. This is a standard limitation which has been removed in special demonstrations.[5]

144. Preferences of Listeners. There is a difference of opinion as to the reason why a typical listener removes the higher pitches of music with his tone control. A careful analysis of various data and procedures in this connection, published by LeBel,[6] should be studied by all who are concerned about the matter.

A direct acoustic test of listener preference for the upper frequencies was made by Olson,[7] the apparatus including no electrical equipment. Original music and speech with a full frequency range were compared with the same sound except that frequencies above 4,000 cps were removed. An acoustic filter, made up of large panels that could be rotated in and out of position, was used with an opaque sound-transparent screen to hide it from the audience. The room had dimensions 24 ft long by 20 ft wide by 9½ ft high. The musical tests were made with a six-piece orchestra in one corner and the listeners in the opposite corner. For speech tests the orchestra was

replaced by one person. Over a thousand listeners participated in the tests and were told that there was a source of music or speech behind the curtain and that the program would be rendered under two different conditions, indicated by the display of letters *A* or *B* on the indicator, and that these conditions would be changed every 15 sec. The listeners were asked to vote on which condition they considered preferable. About two-thirds of the observers preferred the wide range, the figures being about the same for dance music, semiclassical music, and speech. At a meeting of the Acoustical Society of America, J. P. Maxfield, formerly of the Bell Telephone Laboratories, reported that with electronic systems free from h-f transients and cross modulation, he had observed listeners to prefer wide-band reproduction. This, he stated, was true for both single-channel and stereophonic systems.

Extension of the upper audio range greatly increases the requirements for low noise and low introduction of harmonics and intermodulation frequencies. If these faults are present, the upper register will detract from, rather than improve, the over-all quality, and the average listener will unhesitatingly turn down the tone control.

145. Fidelity of A-m and F-m Receivers. The 10-kc spacing of stations in the standard broadcast band places a definite upper limit on the reproduction of the higher audio frequencies. This is 4,000 or 5,000 cps for distant reception and may be substantially higher for strong local signals.

When one end of the audio range of the receiver is restricted, the most natural results are obtained by proportional restriction at the other end of the frequency range; *i.e.*, the l-f range should be extended downward in the same relative proportion as the upward extension of the h-f range. A common working rule is that the product of the lowest and highest frequency limits should be approximately 500,000. Table 13 gives typical ranges[1] and the corresponding frequency product for four types of receivers.

Table 13. Audio-frequency Ranges of Typical Receivers*

Type	Lower frequency limit	Upper frequency limit	Frequency product
Small table set	190	2,700	514,000
Large table set	140	3,500	490,000
Typical console	100	4,500	450,000
High-fidelity console	80	6,600	528,000

* Hanson, O. B., Comments on High Fidelity, *Electronics*, **17**, 130, August, 1944.

If the frequency range goes above 8,000 cycles, an a-m receiver is likely to bring in "monkey chatter," produced by undesired side frequencies beating with the desired carrier or by an undesired carrier beating with the desired side frequencies. It is only with very strong local signals that high-fidelity reception above 8,000 cycles can be enjoyed. In this case the next hurdle is the 10-kc whistle between carriers on adjacent channels; this can be removed with a band-elimination filter.

To obtain a receiver that will produce fairly high-fidelity output on local stations and still be useful for the reception of distant signals, variable selectivity should be provided.

An a-m receiver intended for high-fidelity reception should have special attention devoted to the last i-f amplifier to avoid overloading at this point. It may be necessary to reduce or remove the a-v-c bias on this stage. The audio signal is, of course, the envelope of the r-f wave, so that overloading, which would distort the envelope, must be avoided.

Another refinement is approximately equal audio and d-c loads for the diode detector. Failure to provide this equality will cause clipping of the output during the

[1] Hanson, O. B., Comments on High Fidelity, *Electronics*, **17**, 130, August, 1944. Clark, W. B., Over-all Audio Performance of Commercial Radio Receivers, *Trans. IRE*, **PGA-7**, 11, May, 1952.

inward modulation (also called the "downward" modulation), so that distortion in the reproduced audio wave will occur, especially for modulation exceeding about 50 per cent.

The f-m transmission standards permit the reception of high-fidelity f-m programs with reasonable care. The design must include provisions for a-m rejection to remove noise and to remove distortion which otherwise would result from a.m. introduced by the rounding of the tops of the selectivity curves of the i-f transformers. Beyond this, the requirements for high fidelity involve only the problems of audio amplification and the loud-speaker.

146. General Requirements for High-fidelity Set. The chief general requirements to be satisfied are as follows:

1. The set must be practically free of hum.
2. The reproduction must be practically free of harmonics and intermodulation frequencies at all volume levels.
3. The electrical characteristics must be practically uniform over a wide audio range.
4. A good loud-speaker must be provided.

Interesting general treatments of these requirements[1] and of corresponding studio and motion-picture techniques[2] may be consulted in the literature.

A critical portion of an audio amplifier from the fidelity standpoint is the output stage because of the high power level.[3] This stage is normally operated push pull to remove the even harmonics and to remove the d-c flux in the output transformer.[4] There is a difference of opinion as to the best general type of tube for the output stage. Some favor triodes, owing to the absence of high-order distortion. Others prefer beam tetrodes, with the addition of negative feedback. If triodes are used, care is needed to avoid overloading of the driver stage that furnishes the input for the final stage.

Whatever tubes are used in the last stage, negative feedback is available as a means of reducing distortion. By this powerful tool quality can be improved with little circuit complication, the only important drawback being the reduction in the gain of the amplifier, which can be restored by higher gain couplings or an additional stage.[5]

147. Intermodulation Distortion. Output-input characteristic can be expressed as a mathematical power series in terms of the first, second, third power, etc., giving the instantaneous output as a function of the instantaneous input signal. The second-power term produces the second harmonic and the sum and difference of the various applied frequencies; the third-power term produces the third harmonic and with two input frequencies also produces outputs of $2f_1 \pm f_2$ and $2f_2 \pm f_1$. Counting the two harmonics, the result of third-power distortion is, therefore, six undesired frequencies. Similarly, in the case of fifth-power distortion, two input frequencies produce their

fifth harmonics and eight intermodulation products. These frequencies resulting from intermodulation are generally inharmonic or discordant and also likely to fall in the middle or upper portion of the audio range, both of which conditions make them quite objectionable. Intermodulation can be quickly measured with suitable equipment.[1]

148. Audio Transformers for High-fidelity Sets. The output transformer coupling the last tube to the speaker is one of the worst offenders from the standpoint of fidelity. For adequate linearity to avoid intermodulation, much more iron is needed in the magnetic circuit. Both the quality and the quantity of iron used must, of course, be considered.

149. Dividing Networks. Conversion of the a-f signals into sound is facilitated by dividing the frequency range into a lower and an upper part with a separate special speaker for each portion. In this case the h-f speaker is often called a "tweeter," and the l-f speaker a "woofer." A filter network[2] is generally provided to route the proper frequencies to each speaker.

Numerous circuit arrangements are available for dividing networks, such as the mere use of series capacitors in the tweeter circuit. More elaborate networks include two filters which may be designed for series or parallel input connection. For the more elaborate designs a choice of the dividing frequency is required, *i.e.*, the frequency at which an equal electrical output is delivered to the two speakers. Above this frequency, the woofer receives decreasing amounts of signal, and below this frequency the tweeter receives decreasing amounts. The networks used in motion-picture practice generally introduce an attenuation of 12 db per octave as the frequency departs from the dividing frequency. Some experimenters favor locating the dividing network between the driver and the last stage, so as to operate at a lower power level. In this case separate output stages are necessary for the two frequency ranges.

150. High-fidelity Loud-speakers. Acoustics and loud-speakers are treated in Chap. 11; only a few points are discussed here.[3] The tweeter is often mounted in the opening of the woofer, a coaxial arrangement with the advantages of compactness and identity of source location for the two ranges of frequencies.

Diffusing vanes for a cone-type tweeter are desirable to correct the beamlike character of the h-f radiation. An example of a coaxial speaker with such vanes is the Altec-Lansing Duplex.[4] This speaker is used with a dividing network having a crossover frequency of 1,200 cps. With a baffle of 6 cu ft volume, good response is obtained down to 60 cps and with 9 cu ft down to 40 cps. The inner surface of the baffle must be covered with sound-absorbent material to prevent reflections that would give a "hang-over" or echo effect. The vanes give the h-f radiation a distribution of 60 deg horizontally by 40 deg vertically.

Electrostatic speaker units of the push-pull type[5] have attractive characteristics for consideration with regard to the upper and medium portions of the audio range. The push-pull feature, which is also called *balanced operation*, offers the important advantage of freedom from second-harmonic distortion. Other advantages of electrostatic types are smooth response-vs.-frequency characteristic, good spatial distribution, and low transient distortion.

VARIABLE SELECTIVITY

151. Types and Properties. Ability to vary the selectivity of a receiver is useful where wide variations in receiving conditions are encountered. In broadcast reception, variable selectivity permits the use of a wide carrier-frequency pass band for the high-fidelity reception of local programs, while upon contraction of the selectivity distant stations can be received free of cross talk. In amateur practice, very sharp selectivity is often required to receive phone and telegraph messages in the presence of intense interference. Amateur receivers generally include variable selectivity[1] with an adjustable quartz-crystal filter. By this means band widths as small as 100 cycles can be obtained.

Variable selectivity is easily obtained in the superheterodyne receiver by a change of the characteristics of the i-f amplifier. Available methods are (1) variation of the coupling between the windings of one or more of the i-f transformers so as to widen the selectivity through over-optimum coupling;[2] (2) introduction of damping, *i.e.*, lowering the Q of one or more of the coupling systems (this has the disadvantage of reducing the selectivity against interference having a frequency some distance from the carrier frequency); (3) detuning the i-f tuned circuits, so as to convert the amplifier to stagger-tuning; and (4) use of an auxiliary feedback tube which can be made to cut down the peak and build up the skirts of the selectivity curve.

Some methods produce symmetrical variation of the selectivity while others produce unsymmetrical variation, the distinction being whether the selectivity curve for the various adjustments is the same or different on the two sides of resonance. In Table 14 the chief characteristics of the two types of operation are given.

Table 14. Characteristics of Symmetrical and Unsymmetrical Types of Curves for Variable Selectivity*

Characteristic	Symmetrical type	Unsymmetrical type
Complication of operation	Only one variable, the amount of expansion	Two variables, *i.e.*, the response on the two sides
Fidelity	Not critical	May be critical because of carrier being near edge of band
Selectivity	Better when comparable interference is encountered on both sides of the carrier	Better when major interference is on only one side
Noise	Minimum	About 3 db above minimum
General usefulness	Superior from fidelity standpoint	Superior from selectivity standpoint

* From Wheeler, H. A. and J. K. Johnson, High Fidelity Receivers with Expanding Selectors, *Proc. IRE*, June, 1935, p. 594.

A laboratory receiver with a continuous manual variation of selectivity was constructed at Hazeltine and is described in a paper[3] by Wheeler and Johnson. This design uses variation of coupling in two i-f transformers, of equal Q, and one additional interstage coupling of $Q/2$ to obtain an approximately flat-topped selectivity curve. The valley between peaks caused by the overcritical coupling of the adjustable transformers is filled in by the single peak of the $Q/2$ transformer. Broadcast receivers with variable selectivity generally provide two or three band widths. One or two small windings are used in each variable transformer to increase the coupling to the desired overcritical value. When only the regular windings are in use, the transformer has critical or slightly undercritical coupling, and the selectivity is sharpest.

[1] Villard, O. G., Jr., and W. L. Rorden, Flexible Selectivity for Communications Receivers, *Electronics*, **25**, 138, April, 1952.

[2] Sturley, K. R., "Radio Receiver Design: Part I," 2d ed., Wiley, 1953; see pp. 517-550.

[3] Wheeler, H. A., and J. K. Johnson, High Fidelity Receivers with Expanding Selectors, *Proc. IRE*, June, 1935, p. 594.

Laboratory receivers have been made in which the selectivity curve automatically expands as stronger signals are tuned in, and contracts as weaker signals are received. In a design described by G. L. Beers[1] triode tubes reduce the Q of various windings of the coupling transformers.

A discussion of automatic selectivity control by H. F. Mayer[2] compares variation of coupling, variation of Q, and detuning, and leads to the conclusion that alteration of the coupling produces the best results for the additional parts required.

By means of an audio tuned circuit, it is possible to isolate the 10-kc beat between the carriers of adjacent broadcast stations and utilize this to increase the selectivity, thus making the receiver selective to a degree depending upon the strength of the interference.[3] This design includes a control tube for each of two i-f stages, the control tube feeding back energy to reduce the peak of the selectivity curve by degeneration and build up the sides by regeneration. For weak signals or strong 10-kc beat, the control tubes are biased toward cutoff. As stronger signals are received, or weaker interference, this negative bias is reduced, thus widening the selectivity.

Another automatic selectivity control[4] includes two traps tuned respectively to the next channel above and the next channel below the carrier frequency. They operate independently to contract the selectivity on the side where interference is experienced. In this way the contraction may be on either side or on both sides.

SINGLE-SIDE-BAND RECEIVERS

152. Advantages and Techniques.[5] The spectrum conservation and other advantages of the single-side-band method led the FCC in 1956 to begin proceedings looking toward the establishment of this feature as a requirement for radiotelephone operation in bands below 25 Mc.

Reception of an SSB transmission is possible in a straightforward manner by the provision of a stable oscillator to simulate the missing carrier. Another method, widely used, depends on phasing operations. In this method the incoming single side band, normally at i.f., is heterodyned separately in two demodulators, one supplied with local injection at reference phase and the other with injection at 90 deg; then the two audio outputs are shifted one ahead 45 deg and the other back 45 deg, with the result that addition of the two audio signals will give the desired signal if the transmission is an upper side band and the difference will give the desired signal if the transmission is a lower side band.

SSB technique has long been used in transoceanic radiotelephony, and advanced methods are utilized to obtain continuity of service and maximum use of the available spectrum.[6] For other services the problem of *compatibility*, that is, operation with both conventional and SSB equipment, may require attention, and it may be desired that a receiver accommodate more than one type of signal.[7]

Transmission with one side band and an amount of carrier inversely proportional to the amplitude of the side band has been successfully demonstrated with experimental equipment in service between airplanes and ground. With this arrangement the full power of the transmitter is devoted to the side band when needed, but at other times

is more or less used for sending carrier which is available for operating a "mechanical" a-f-c system.[1]

For mobile land service at 160 Mc with channels of the order of 15 to 30 kc, phase-modulation technique appears to afford more service from a limited number of channels than would SSB suppressed-carrier technique.[2]

AUTOMOBILE RECEIVERS

153. Characteristics. The automobile set differs from home sets in that:

1. A small whip antenna is used.
2. Limited space in the car requires compact construction.
3. Vibration and wide temperature range necessitate rugged parts and construction.
4. Inductive tuning of the r-f and oscillator circuits is generally used.
5. The 6- or 12-volt storage battery serves as power supply.
6. Severe disturbance of the engine ignition requires thorough shielding and by-passing.
7. Metal housing is used, generally single-unit.

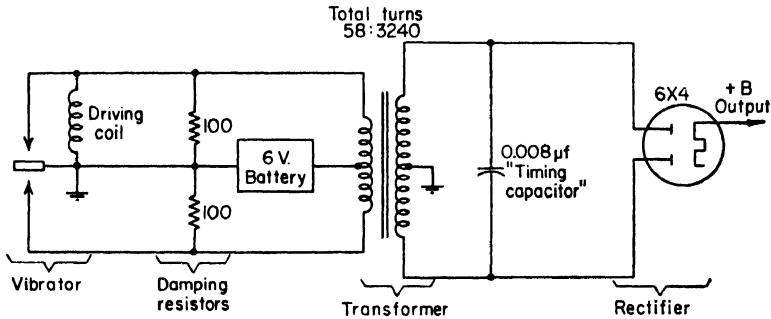
The conventional automobile-receiver design includes one r-f stage, inductive three-gang tuner for the antenna, interstage, and oscillator circuits, a.v.c., one i-f


FIG. 36. Typical shunt-coil type of vibrator with stepup transformer and rectifier tube for furnishing plate-supply voltage. The battery can be connected with either polarity.

stage operating at either 455 or 262 kc, a tone control, permanent-magnet dynamic speaker, and power supply consisting of vibrator, transformer, and tube rectifier.[3] Push buttons for choosing preset stations are often provided, the most frequent number being five. These usually operate mechanically to set the inductive tuning gang at the desired position.

Antennas are generally short whip types of low capacitance and limited signal-collecting ability. Dummy antennas to represent these vary from single series capacitors of 40 to 100 $\mu\mu$f to series-shunt capacitor arrangements. In the latter case the series capacitor is connected to the signal generator and the shunt capacitor is connected across the input terminals of the receiver. The values of the capacitor elements lie in the range from 30 to 60 $\mu\mu$f.

The vibrator[4] in the plate-supply circuit commutates the d.c. from the battery so that flux in the transformer reverses direction in step with the moving reed. The frequency is standardized at 115 ± 7 cps. The transformer steps up the voltage, which is then rectified to serve as the desired plate supply. Typical connections for operation with a 6-volt battery are shown in Fig. 36.

Search tuning for an automobile receiver can be provided without a.f.c. by means of the following mechanical and electronic features: (1) a spring-operated or motor-operated mechanism which can move the normal station-selecting carriage and which if not interrupted will scan the entire broadcast band in about 5 sec; (2) a trigger circuit associated with the a.v.c. in such a way as to stop the sweeping action when a signal of adequate strength is received; (3) a push button or bar which the user can press, thus instructing the receiver to discontinue receiving the particular station and search for another station; and (4) an automatic end-of-the-band return switch whereby the carriage is rapidly sent to the other end of the band whenever needed.[1] This type of operation is quite useful for a driver visiting different areas because the receiver will quickly bring in the various stations which are available in each particular area. The feature can, of course, be provided in addition to the usual push buttons which are normally set to stations in the home territory.

The use of one or two transistors as the output stage of an automobile receiver is discussed in Sec. 38. Designs with this feature can utilize the line of tubes requiring only 12 volts plate supply and thus, with a 12-volt automobile battery, eliminate the vibrator, power transformer, and rectifier of the previously conventional receivers. This line of tubes[2] includes the 12K5, a space-charge tetrode which can deliver the appreciable driver power required by the output stage. Another tube for this service is the 12J8.

The lower-power stages of such an automobile receiver, operating with 12 volts as both heater and plate supply, can utilize the 12AC6, 12AF6, or 12CX6 pentodes in the r-f stage, the 12AD6 heptode converter, various types including the 12CN5 for i-f stages, and the 12AE6, 12F8, or the 12CR6 for detection, a.v.c., and first audio amplifier. A caution has been issued that these tubes should not be tested on the usual emission type of tube checker because of the danger of permanent change of contact-potential conditions.

For a discussion of phonograph operation in automobiles see Sec. 117.

V-H-F AND HIGHER BAND RECEIVERS[3]

154. General Considerations. As receiver designs are made for the v-h-f range and above, various differences in the general conditions which prevail are found. Specially noticeable are (1) the increase of tube input conductance, (2) the smaller amount of atmospheric disturbance and of man-made interference, and (3) the desirability of handling greater band widths. The increase of the input conductance causes lower voltage gains in the coupling circuits. The reduced atmospherics and interference make weaker signals potentially usable. The greater band widths mean that sources of noise in the resistors and tubes of the receiver will produce greater noise power. The result of all these factors is that noise originating in the receiver is a major problem; in fact the design of front ends for receivers for these frequency ranges is largely a matter of obtaining adequate signal-to-noise ratio.[4] Representative noise factors for receivers specially designed for good performance in this respect are 4 db at frequencies up to 100 Mc, 9 db at 1,000 Mc, and 14.0 db at 10,000 Mc.

At increasingly higher frequencies, the input conductance of tubes, when operated in the grounded-cathode manner, becomes greater as a result of two causes. One is the presence of inductance in the cathode lead which is common to the input and output circuits of the tube. This is often minimized by the provision of two separate leads from the cathode to separate pins in the base of the tube, one of these being used for the input circuit and the other for the output circuit. Another cause of increasing input conductance is the transit-time effect resulting from the fact that the signal potential on the control grid changes appreciably in the time required for electrons to go from the cathode space charge to the grid, resulting in the signal on the grid doing work on the electrons and thus abstracting energy from the source of the signal and increasing the input conductance of the tube. The conductance due to both the lead-inductance and transit-time effects is proportional to g_m and to f^2. Tripling the frequency causes the input conductance to increase to nine times its previous value.

Since the noise power produced by tubes increases with the band width, the narrower the band, the higher the frequency limit at which any particular type of tube will work. A given tube will work satisfactorily as an oscillator at frequencies considerably above its limit as an r-f amplifier. For amplifier service there is a constant product of the obtainable values of gain and band width, as discussed further in Sec. 194.

Superregenerative detectors for operation at 30 to 3,000 Mc have proved serviceable in various military equipment. For further data see Sec. 159 *et seq.*

Receivers for the frequency ranges now being considered have i.f.s from 5 to 200 Mc.[1] Values of 30 and 60 Mc are widely used in radars. The i-f band widths in various services have values up to 25 Mc. The wider band widths are obtained by staggered tuning or by the use of special feedback arrangements (see Sec. 77).

Superheterodyne frequency converters for receivers operating in these frequency ranges are discussed in Secs. 55 to 57.

155. Use of Lumped-constant Circuits. It is often found that satisfactory tuning control can be obtained by switching in fixed wide-band antenna circuits and r-f tuned circuits upon change of band and varying only the oscillator frequency in tuning from station to station.[2] In a receiver having a band of relatively wide frequency coverage and having low i.f., this technique would lead to objectionable image interference. However, if the limitations are borne in mind, this technique may be found a valuable method. It has been widely employed.

The circuit between an antenna and a conventional grounded-cathode r-f stage can advantageously be given a slight overcoupling in the interest of improved signal-to-noise ratio. This increases the skirt selectivity and thereby removes some noise in the outer frequency regions where no signal components exist.

When conventional coils and capacitors are applied at higher frequencies, a point is reached where the capacitance has been reduced to only that inherently present in the tube, socket, wiring, and coil, and the inductance is as small as possible for the required L/C ratio. Upon replacement of the tube, therefore, there will generally be a different input capacitance, the difference being a large enough fraction of the total circuit capacitance to render inaccurate a calibrated tuning dial or to disturb a unicontrol arrangement. Reduction of the tuning capacitance to where it consists only of the inherent minimums also has the objection that if a.v.c. is applied to the stage, the resulting variation of tube input capacitance may cause excessive detuning.

Another available design for frequencies up to 200 or 300 Mc is the grounded-cathode triode in a push-pull circuit. Laboratory work by William F. Bailey (Hazeltine) has shown that a 6J6 double triode can be cross-neutralized in the conventional transmitter fashion and good gain and signal-to-noise ratio thus obtained. However, the method has the drawback that the stage may require readjustment of the neutralization when a tube replacement is made.

[2] As an example in amateur practice, see B. C. Barbee, A Compact and Inexpensive Superhet for 144 Mc, *QST*, October, 1947, p. 33.

156. Triodes in Grounded-grid Circuit. For signals from about 100 Mc, advantages may be found in the grounded-grid triode[1] as an r-f amplifier, especially if the receiver is intended for wide-band operation. In the grounded-grid amplifier the high side of the input connection is made to the cathode and the low side to the grid, which is grounded. The output is taken between plate and ground in the normal manner. Analysis shows that the input and the output currents are about equal, so that the amplifying action of the tube can be considered as reproducing the input current but at a higher voltage and out of a higher impedance.

The gain of a grounded-grid tube is

$$\text{Voltage gain} = \frac{R_L(\mu + 1)}{R_p + R_L}$$

where R_L = load resistance, ohms
μ = amplification factor of tube
R_p = internal plate resistance of tube, ohms

If the load resistance is much less than the internal tube resistance and if μ is much greater than unity, the gain simplifies to $R_L g_m$.

The value of the grounded-grid stage lies essentially in the fact that the input and the output circuits are fairly well shielded from each other, as in a screen-grid tube, while at the same time the low noise level characteristic of a triode is retained. Another advantage, which is important, is that the grounded-grid stage has an input conductance which is fairly constant with frequency, being

$$g_i = \frac{\mu + 1}{R_p + R_L}$$

If μ is much greater than unity and if the load resistance R_L matches the internal tube resistance R_p, the input conductance is $\mu/2R_p$, or $g_m/2$. If the load resistance is small compared with R_p and μ remains much greater than unity, the input conductance is μ/R_p, or g_m. Since the input conductance of a pentode increases steadily with frequency, there is a frequency above which the grounded-grid triode has lower input conductance than the pentode.

Slightly less than critical coupling into a grounded-grid stage gives the best signal-to-noise ratio.

The 6J4 miniature triode is useful for grounded-grid operation and is rated up to 500 Mc for this service. It has a low value of plate-to-cathode capacitance so as to reduce the feedback from output to input circuit inside the tube. A striking application of this tube was made in the radar receiver used to obtain echoes from the moon at 111.5 Mc. This receiver achieved a noise figure of only 5 db for the front end of the set. For further data on this receiver see Sec. 46.

For tuning in the general region of 300 to 1,300 Mc, especially over limited ranges, transmission lines[2] can be used. A $\lambda/4$ line shorted at the far end acts as a parallel tuned circuit at the near end. Other lengths of shorted line are available for use as high-Q inductors or capacitors. Carefully made transmission lines can be constructed to have the desired reactive characteristics and to have low losses. Balanced parallel-rod lines can be used up to 600 or 700 Mc, and coaxial types above this.

As signals above 400 or 500 Mc are to be received, it becomes advantageous to change from the conventional type of tube to the planar type, and usually at the same time to employ a coaxial type of transmission line for tuning rather than the parallel-rod type. The planar tubes are so-called because the active surfaces of the elements are planes, and include the "lighthouse" series (such as the 2C40)[3] and the Western Electric Type 416-B.[4] For amplification up to 1,000 Mc and oscillation

up to 3,000 Mc good performance is also afforded by the cylindrical-structure "pencil" types of triodes.[1]

The short lengths of coaxial transmission lines and the large circular contacts required for connection to these u-h-f tubes give equipment of this type an appearance which has led to the term "plumbing" as the usual informal name. The characteristics and name continue to apply with preselectors and local oscillators of the transmission-line or wave-guide type up into the s-h-f range.

157. Butterfly Tuners.[2] Tuners of the butterfly type, such as shown in Fig. 37, are continuously adjustable over a wide frequency range, designs of moderate size achieving ratios as great as 5:1 in frequency and larger designs achieving greater ratios. These tuners have been made and used at frequencies as low as 40 Mc and as high as 1,100 Mc or more. The construction is somewhat similar in appearance to a variable capacitor, with the exceptions that (1) the circuit inductance is built in, consisting chiefly of the circular-strap portions of the stator plates, (2) both connections are made to the stator, whence (3) there are no sliding contacts. When the rotor is turned toward increased meshing, the frequency is lowered by (1) increased inductance, resulting from removal of the conducting rotor plates near the inductive straps, and (2) increased capacitance in each of the two series capacitors (one-terminal-to-rotor and rotor-to-other-terminal) constituting the capacitive element of the tuner. The rotor turns through an angle of 90 deg for its full frequency range.

Fig. 37. Butterfly tuner. P_1 and P_2 = points for electrical connections; R = rotor; S = stator.

One design of butterfly tuner covering the range from 220 to 1,100 Mc has the characteristics shown in Table 15. This design has a diameter of 2½ in. It has 0.04-cm clearance between stator and rotor plates as they mesh, so that high voltage and power cannot be handled. It has five rotor and six stator plates.

Butterfly tuners are suitable for use where wide frequency ranges must be handled. In design for such service, the size and number of plates are made as large as possible while still getting the necessary top frequency and freedom from spurious modes of operation. The necessary l.f. is then obtained by reducing the air-gap clearance as far as required.

Table 15. Characteristics of Butterfly Tuning Element Covering Range of 220 to 1,100 Mc

Frequency, Mc	220	1,100
Inductance, μh	0.011	0.004
Capacitance, μμf	48	5
Q	650	300
Impedance, ohms	9,800	8,600

158. Technique for Frequencies Where R-f Stage Cannot Be Used. At some point in the frequency band between 500 and 3,000 Mc, it is found that the use of an

[2] Karplus, Eduard, Wide-range Tuned Circuits and Oscillators for High Frequencies, *Proc. IRE*, July, 1945, p. 426.

r-f stage in a receiver results in lower gain or lower signal-to-noise ratio than without the stage.[1] Klystrons will produce amplification at these frequencies and are useful as transmitting amplifiers, but they are too noisy for use in receivers.

The receiver for frequencies above this point, therefore, has as its first elements the antenna, a passive coupling circuit, a superheterodyne oscillator, and a silicon-crystal mixer for converting the signal to i.f. A simpler type, called a *crystal video receiver* and analogous to the t-r-f receiver formerly used for broadcast reception, consists of only an r-f coupling circuit, detector, and the modulation-frequency or "video" amplifier; there is no local oscillator, mixer, or i-f amplifier. Such crystal video receivers are used for radar beacon service and other cases where small lightweight equipment is required.[2]

The reflex klystron[3] is generally used as the oscillator for receivers in the s-h-f range. The likelihood of requiring a.f.c. is apparent when it is noted that a band width of 10 Mc at a carrier frequency of 10,000 Mc amounts to only 1 part in 1,000. A.f.c. is therefore generally provided, the control system operating by placing on the reflex electrode of the klystron a suitable voltage so as to keep the i.f. of the receiver at its proper value.

For wide-band reception, such as for narrow sharp pulses, in this frequency range, extensive design procedures from the television and radar[4] arts are available and are described in Secs. 194 to 196. Pulses as short as 0.006 μsec, corresponding to less than 10 ft of path length in the transmission medium, have been produced and utilized for checking the quality of wave guides at 9,000 Mc. The receiver for these pulses consisted of three cascaded traveling-wave stages as r-f amplifiers, the detector, a distributed type of video amplifier, and a special oscilloscope.[5]

Considerable interest has been shown in the traveling-wave tube described by Kompfner in England[6] and Pierce and Field[7] in the United States. An experimental tube of this type made at the Bell Laboratories furnishes substantial amplification over the very wide band width from 3,200 to 4,000 Mc. For transmitting purposes the tube will furnish substantial amounts of power, and its noise characteristics are satisfactory. To adapt it for receiver use extensive efforts have been directed toward the perfection of quiet electron guns so as to obtain lower noise factors.[8] The RCA type 6861 has a noise factor of only 6.5 db with a gain of 25 db for the entire band from 2,700 to 3,500 Mc.

Designs of traveling-wave tubes for 50,000 Mc have had gains of 19 db, and for 58,000 Mc gains of 9 db, with noise factors in the region of 25 to 30 db.[9]

A combination of a traveling-wave tube and an oscilloscope, called a *wamoscope* (for wave-modulated oscilloscope), has been developed and affords an almost complete receiver in the single glass envelope. The Sylvania type 6762 is about 23 in. long and can be used at any frequency from 2,000 to 4,000 Mc. The output beam from the traveling-wave portion of the tube enters an electron-optical system which acts as a velocity-sorting detector; from here the beam goes on to the fluorescent screen as in the usual oscilloscope tube.

An important feature of microwave practice is the use of suitable ferrites in wave guides for such purposes as rotating the plane of polarization and thus acting as an attenuator.[1]

SUPERREGENERATIVE RECEIVERS

Superregeneration offers high gain, such as 100 db, in a single tube. Fundamentally a method of amplification, it is easily adapted to performing a-m detection also and has been very frequently used with this additional feature. On account of the high gain obtainable, it is possible to make a set of high sensitivity with only a few tubes. Superregeneration, described by Edwin H. Armstrong in 1922,[2] was little used except in amateur v-h-f receivers until the Second World War, when it was employed extensively in military equipment. Subsequently it was given further careful study.[3]

159. General Principles. The superregenerator tube is provided with ample feedback so as to be capable of oscillation at the desired r.f. It is also provided with a periodic quench voltage by which an oscillation which has built up is stopped for a time, after which the quench is removed and an oscillation builds up again. In this way the circuit is prevented from going into permanent oscillation; instead it engages in a periodic building up of transient oscillations whose average value depends upon the signal voltage existing in the circuit when each build-up starts. Thus amplification is produced. Superregeneration can therefore be considered as a sampling process by which samples of the signal are taken at quench-frequency intervals and much amplified. This process is sufficient to recreate the envelope if the highest modulation-frequency component of the signal is less than half the quench frequency.

In case no signal is present, fluctuation noise will start the oscillations, and this noise will therefore be amplified by the superregenerative action. However, impulse noise, which occurs at discrete instants, generally does not coincide with the sensitive periods of the superregeneration, so that most of the impulses are suppressed.

For purposes of analysis and design, the action of the superregenerative tube can be considered as presenting to the tuned circuit a negative resistance, or the equivalent negative conductance, during the build-up time. Conversely, during the quench interval the circuit has loss corresponding to a positive conductance. The result is that the conductance of the tuned circuit varies with time at the quench frequency. H-f oscillations build up during the period of negative conductance and decay during the following period of positive conductance. The conductance-time characteristic is one of the fundamental quantities determining the performance. Another important quantity is the total tuned-circuit capacitance.

The quench voltage can be provided by a separate oscillator, in which case the circuit is described as having "separate quench." Certain operating features are obtainable only in this way. Often, however, the superregenerative tube is provided with a suitable grid leak and capacitor so that its oscillations block periodically, thus ena-

bling the tube to serve as its own source of quench voltage. Such operation is described as "self-quenched."

There are two distinct modes[1] of superregenerative operation: the linear and logarithmic.

In the linear mode the quench frequency and other factors are so proportioned that the quench voltage acts to stop the building up of oscillations while they are still rising; *i.e.*, the oscillations do not reach the maximum amplitude at which the tube would operate if it were in a steady state of oscillation. The linear mode is given this name because the amplitude reached is proportional to the signal amplitude at the start of the build-up period; in this way there is a linear mathematical relation between output and input. Separate quench is required for the linear mode.

In the logarithmic mode the oscillations are allowed to build up to the maximum amplitude of which the tube is capable before the quench voltage is applied. Build-ups starting from various signal strengths are, however, not identical, because one started by a strong signal has a larger value throughout the entire build-up period and reaches the maximum value sooner than one starting from a weak signal. The modulation-frequency signal obtained upon detection is found to be proportional to the logarithm of the input signal amplitude, so that this type of operation is called the "logarithmic mode." This mode can be obtained with either separate or self-quench.

The three possible types of superregenerative circuits with respect to mode and quenching are shown in Table 16.

A logarithmic-mode superregenerator can easily be adapted to perform a-m detection in addition to superregenerative amplification, by providing an impedance in either the grid or plate circuit across which the m-f voltage can be developed.

In self-quenched operation the quenching action can occur only as a result of the oscillations building up to the maximum amplitude which is possible under the particular conditions. Such operation is therefore always of the logarithmic mode. With

Table 16. Main Classification of Superregenerative Circuits with Respect to Mode and Quenching

Quench	Mode	
	Linear	Logarithmic
Self-quench	Impossible	Often used. See Sec. 162.
Separate quench	Often used. See Sec. 160.	Can be used. See Sec. 161.

a strong signal the maximum amplitude is reached sooner, the quench voltage comes on sooner, and after the usual quiescent period, the next build-up of oscillations is sooner—all in comparison with the action for a weak signal. Therefore, the quench frequency varies in self-quenched operation, the value rising and falling with the amplitude of the signal.

If a superregenerative receiver oscillates at or near the signal frequency, it may be an objectionable source of radiation to other nearby receivers tuned to receive the same transmission. This radiation can be reduced by using an untuned shielded r-f stage ahead of the superregenerator.

The wave form of the quench voltage may be of several different shapes: sine-wave, rectangular, trapezoidal, saw-tooth, etc. The resulting curve of circuit conductance as a function of time will vary accordingly, and the performance may thus be considerably affected. As an example, selectivity is better for sine-wave quench than for rectangular-wave quench.

[1] Frink, F. W., The Basic Principles of Superregenerative Reception, *Proc. IRE*, January, 1938, p. 76.

Values of the quench frequency vary considerably according to the particular service, with a range of at least 15 to 2,000 kc.

160. The Linear Mode. Operation in the linear mode requires a separate quench. The gain in this case and the selectivity for either the linear or the logarithmic mode are obtainable from a knowledge of the circuit-conductance curve and the total circuit capacitance. The superregenerative gain is $4.35a/C$ db, where a is the area of the negative-conductance portion of the conductance-time curve (Fig. 38) and C is the total circuit capacitance.

Example: If a is 325×10^{-12} mho-sec and C is 20 $\mu\mu$f, the superregenerative gain is 70 db. This is to be added to the nonregenerative gain in the input coupling system and to the regenerative gain. Thus, if the nonregenerative gain is 20 db and the regenerative gain is 14 db, the total gain would come to an over-all figure of 104 db.

Fig. 38. Trapezoidal quench wave showing quantities which determine the sensitivity and selectivity of a superregenerator.

The band width for either linear or logarithmic operation, measured at 8.7 db (1 neper) down, is given by

$$\frac{1}{\pi}\sqrt{\frac{g'}{C}}$$

where g' is the rate (expressed as a positive quantity) at which the conductance is changing when the sign of the conductance changes from plus to minus, and C is the total capacitance of the circuit. This formula can be used with saw-tooth, trapezoidal, and sine-wave quenches, but not with square-wave quench; *i.e.*, the value of g' must not be too large. In particular, this formula is useful when the value of g' is less than $G^2/4C$, where G is the absolute value of the conductance at the end of the straight-line portion of the conductance-time curve, as shown in Fig. 38.

Example: If g' is 200 mhos per sec and C is 20 $\mu\mu$f, the 8.7-db band width is 1 Mc. The value of $G^2/4C$ is 405, so that the criterion for the applicability of the formula is satisfied.

Further information regarding band width is obtainable from the fact that the selectivity curve has the shape of a probability curve between the nose and a value of attenuation equal to $2.2GT/C$ db, where G and T (= time) have the values at the point indicated by a dot on the conductance curve of Fig. 38. Assuming, in the typical example, that the value of T is 0.9 μsec, the formula gives 18 db. In other cases this may amount to 40 to 80 db.

A probability curve has a shape corresponding to the selectivity of a large number of isolated single-tuned circuits in cascade. A superregenerative receiver can, therefore, have a selectivity curve with very steep sides. By comparison with the selectivity obtainable in conventional multicircuit receivers, the probability curve is somewhat broad near the resonant frequency; yet it has good skirt selectivity, which means good rejection of unwanted signals outside the pass band of the receiver. For the best selectivity a saw-tooth quench wave can be used with the gradual change from positive to negative conductance and the rapid change in the opposite direction. This decreases the value of g' and increases the value of T.

Automatic gain stabilization can be included in these receivers to maintain reception despite changes of antenna impedance, line voltage, tube aging, and the effects of high humidity. The system operates by detecting the quench-frequency pulsation of the r-f signal in the superregenerative circuit, amplifying it, rectifying it, and using the resulting d-c voltage to control the superregenerative tube. This maintains the quiescent noise output almost constant, in addition to keeping the general operation within good limits.

The sensitivity of a linear-mode superregenerator increases as the amplitude of the
quench voltage increases, but the quench amplitude must not be great enough to overload the tube. Sensitivity also increases as the frequency of the quench voltage is lowered. Selectivity increases, *i.e.*, band width decreases, for both lower frequency and lower amplitude of quench voltage. It is seen therefore that sensitivity and selectivity improve with lower values of the quench frequency. The requirements of sensitivity and selectivity with regard to amplitude are however opposed, low amplitude favoring selectivity and high amplitude favoring sensitivity.

161. Logarithmic Mode with Separate Quench. Theoretical and experimental studies of superregeneration of the logarithmic mode with separate quench have been made. There is considerable amplitude distortion with the logarithmic mode because a large increase of signal causes only a slight increase in the output due to the logarithmic output-input relationship. This is advantageous in reducing the effect of impulse noise, but produces considerable distortion in a-m reception. For headphone listening to speech signals the modulation under these conditions should therefore not exceed about 80 per cent.

162. Self-quenched Circuits in A-m Reception. All self-quenched circuits operate in the logarithmic mode, and the quench frequency is a function of the signal amplitude.

The self-quenched superregenerator has been extensively used in amateur practice, triodes such as the 6J5, 7A4, 9002, and 6C4 being employed with grid leaks of 2 to 10 megohms and grid capacitors of 50 to 100 $\mu\mu$f. The 6F4 is also very suitable. Quench frequencies have varied from 20 to 250 kc as the center value, with frequencies of 150 to 250 kc recommended for signals at 60 Mc and higher in the v-h-f range.

One refined amateur superregenerator[1] includes an untuned 6AK5 r-f stage and achieves a substantial reduction of radiation.

RECEIVERS FOR PULSE-TYPE COMMUNICATIONS

During the Second World War and the postwar period, there was an increasing realization that there are advantages in the use of pulses for general communication purposes,[2] such as multiplex telephony. Such a system utilizes the principle of sampling; *i.e.*, the signal wave to be transmitted is sampled at a frequency at least twice the highest component, so that the reproduced wave will be a satisfactory copy of the original.

163. Pulse Systems. Two of the several possible types of pulse systems are of importance: (1) pulse-time modulation (called PTM, or PPM for the alternative name pulse-position modulation) and (2) pulse-code modulation (PCM, also called pulse-count modulation). Both types use pulses of substantially rectangular shape and of constant amplitude. Since the sampling is at a frequency two or more times the highest signal component and since a number of harmonics are necessary to create the rectangular shape, the band width required by pulse systems is many times that needed in the conventional types of modulation. However, there are compensating advantages: (1) These systems are highly resistant to the effects of noise so that lower transmitting power can be used or a greater distance be obtained, and (2) in multiple operation where several messages are being sent simultaneously, nonlinear amplifiers can be used without danger of cross talk between the individual channels. It will be seen that these systems with pulses of constant amplitude have characteristics similar to telegraph practice where "regenerative" repeaters have long been used, the term "regenerative" referring to the restoring of the pulse shape in addition to the amplification in the repeater. On account of the simplicity of the wave shape, repeaters in pulse systems can produce such regeneration, so that the noise is substantially removed at each repeating point. In PTM and PCM systems the signal-restoring benefits

realized in telegraph practice can be obtained also in the much faster operations required for the transmission of signals for voice, facsimile, etc.

An important increase of the effective selectivity of a pulse receiver can be obtained by an invention[1] of the late R. B. J. Brunn. This utilizes the fact that a pulse of carrier frequency, according to Fourier analysis of the modulating wave, includes side frequencies near the carrier representing the pulse duration and the amplitude in the middle of the pulse and also includes well-spaced side frequencies representing the abrupt start and end of the pulse. If, therefore, such a pulse is detuned because it is at an interfering carrier frequency, the close-in side frequencies will be reduced, while the well-spaced ones on one side may be transmitted in fair amplitude. The effect of the selectivity is then to change the pulse shape from rectangular to a lower average level plus spikes, or ears, at the start and end. After detection, stabilization can be used to bring all positive peaks to the same level, and further processing will leave the undesired pulse represented only by spikes while the desired pulse has its normal shape. The use of a coincidence mixer then eliminates the spikes and delivers a useful output from the desired pulses.

164. Pulse-time Modulation. One method by which audio signals can be transmitted with pulses is by varying the position or time of successive pulses, each with respect to a reference pulse which occurs at a regular rate. Thus modulation is attained by displacing the signal pulse from its normal position or time by an amount proportional to the amplitude of the modulating signal. For example, if the pulse occurs later than normal, the audio amplitude may be positive; if the pulse occurs earlier, the amplitude will then be negative. It is possible to use a single reference pulse for numerous signal pulses, each signal pulse representing a different voice or other transmission so that multiplex operation is obtained.[2]

The effect of noise in a pulse-time system is limited to the extent to which it influences the time of occurrence of the signal pulse. As a result, the steeper the edges of the signal pulse, the less the influence of noise. Therefore, with increase of band width, which permits steeper slopes, noise has less effect on transmission. This system, therefore, obtains improved signal-to-noise ratio at the expense of greater band width.[3]

165. PTM System of 24 Channels. A 24-channel PTM system, developed by the Federal Telecommunications Laboratories,[4] required the transmission of modulating signal components up to 2.8 Mc. This system, suitable for use over a coaxial cable or over a radio link, utilizes pulses of 0.5 μsec duration, two of these with a 1.3-μsec separation constituting the marker pulse. Each signal pulse varies in position over a 2-μsec range in a 5-μsec time channel. Each of the signal channels is sampled 8,000 times per sec, corresponding to a 125-μsec interval. This 125 μsec is divided into 5-μsec time channels to accommodate the 24 multiplex channels and the marker channel. The frequency of pulses, including those for all channels, is therefore 8,000 × 25 = 200,000 cycles, or 200 kc, so that the band width of 2.8 Mc includes the first 14 harmonics and permits a fairly good reproduction of the rectangular pulse shape.

The Federal PTM system includes two Cyclophon tubes, one of which is used as the commutator in the modulator of the transmitter. The other is used as separator and demodulator in the receiver. This tube is a modified cathode-ray tube in which the beam is whirled around in a circular path where it goes through successive holes in an aperture plate and falls on individual "dynode" plates connected to the various channels. The system has been operated by radio[5] in the u-h-f range of 1,225 to 1,325 Mc. The receiver utilizes a 1N23B crystal mixer and a 2C43 oscillator. An

image rejection of 72 db and a noise factor of 14 db are obtained. The i.f. is 30 Mc. The band width at 1 db down is 8 Mc so that the 2.8-Mc maximum signal frequency, corresponding to 5.6 Mc for both side bands, is easily accommodated.

166. Pulse-code Modulation.[1] The method of sampling which characterizes all pulse-type communication systems is used in pulse-code modulation with the additional feature that, after a sample is taken, it is quantized; *i.e.*, a determination is made as to which one of a definite number of amplitude classes it falls into. The number of these classes is some power of 2, such as $2^4 = 16$, $2^5 = 32$, etc., the particular number depending on the design of the system.

However, for the purpose of explanation, assume that only four classes are provided, which is 2 raised to the second power. In this case the four available amplitude classes consist of two for positive values of the signal and two for negative values. The four classes are transmitted by two pulses, two being the exponent. The four classes consist of (1) both pulses present, (2) only the first pulse present, (3) only the second pulse present, and (4) both pulses absent.

It has been found by experiment that satisfactory commercial telephone quality can be obtained by the use of a five-pulse system, which gives 2^5 or 32 amplitude classes. Of these, 16 are positive and 16 negative. Since the range of volume to be accommodated is about 60 db, this corresponds to approximately 2 db per amplitude class. Tests have shown this degree of quantizing to give a 33-db value of the signal-to-noise ratio; *i.e.*, some "quantizing noise" is present and prevents the signal-to-noise ratio from having a larger value.

In PCM the particular signal amplitude at a given moment is represented by the presence or absence of the individual pulses in a group of pulses. As an example, in a five-pulse system, if the first, third, and fifth pulses are present and the second and fourth pulses are absent, a particular amplitude value is indicated.

PCM is therefore characterized by the fact that all pulses transmitted have equal amplitude and equal duration; also (with the exception that certain pulses are omitted) they occur at equal intervals. Under these circumstances, noise is ineffective unless it is sufficiently strong to cause a pulse to appear where none was transmitted, or vice versa. This system is therefore highly resistant to noise and, under typical operating conditions, received signal strengths can be weaker than with other systems. At each repeater the restoring type of amplifier sends on the signal entirely free of noise; *i.e.*, noise is noncumulative as long as the incoming signal-to-noise ratio is above a modest threshold value.

In a typical system using five pulses or 32 amplitude values, the band width is somewhat less than five times that required for a pulse-amplitude-modulated system. This is the cost in band width to obtain the very large increase in ability to withstand noise.

On account of the complexity of the PCM equipment required to code the amplitudes at the transmitter and decode them at the receiver, the system is of special interest in connection with multiplex transmission, a time-division system being used in which the five pulses of one channel are transmitted, then the five pulses of the next channel, etc., the entire system operating with short pulses and short spacings so as to return to the first channel after an interval of 1/8,000 sec or 125 μsec. In a system having eight channels, this means that pulses are transmitted at the rate of $5 \times 8{,}000 \times 8$ or 320,000 per sec.

MOBILE RECEIVERS

167. General Technical and Regulatory Aspects.[2] Communication requirements of mobile services such as police, taxis, fire departments, public utilities, forestry

[2] Macdonald, A. A., Comparison of Split Channel FM and Single Sideband for Land Mobile Services.

services, etc., differ among themselves, but in general the receivers follow conventional engineering practice with certain special features, such as (1) fixed-frequency operation, (2) location of the r.f. generally in the v-h-f range, (3) squelch (see Sec. 93) to keep the loud-speaker quiet between messages, and (4) convenient arrangements for changing between reception and transmission. Mobile radiotelephone apparatus often has facilities for the selective calling of particular cars and for tying into the general wire telephone system.

The regulations of the FCC governing these services in 1957 permit amplitude modulation with a total bandwidth of 8 kc for the two side bands and a 70 per cent normal modulation, or frequency modulation with a total band width of 40 kc and not over ±15 kc deviation. (However, frequency modulation is not permitted on carrier frequencies below 30 Mc.) With either type of modulation, the maximum audio frequency permitted to be transmitted is 3,000 cps.

Various ranges of carrier frequencies are allocated to the different mobile services by the FCC, but in general all these bands are severely congested. To provide additional channels in the region of 160 Mc, the Commission has adopted the rule that after October, 1958, all equipment produced must be capable of narrow-band operation, *i.e.*, operation with 15- or 30-kc channels instead of 60-kc channels as previously.[1]

Standard test procedures for mobile receivers differ substantially from those applicable to broadcast receivers and require careful attention by the designer of mobile types.[2] For example, the standard signal for testing the sensitivity of f-m receivers has a modulation of 70 per cent of full system deviation and a modulation frequency of 1,000 cps. Selectivity is measured with a two-signal method. Intermodulation is determined in terms of effect on the signal-to-noise ratio, and the measurement requires three signal generators.

Substantial amateur experience in mobile communications, including reception, suppression of automobile interference, and other phases, is available in the literature.[3]

168. Police Service. The usual police service installed in recent years operates with phase modulation, equivalent to f.m. with a preemphasis of 6 db per octave. Two-frequency operation is the general rule, with one frequency for headquarters-to-cars transmission and the other for cars-to-headquarters transmission. Car-to-car feature is then obtainable by having a double-frequency transmitter or a double-frequency receiver in each car. In extensive systems, several receiving stations are necessary, the signal picked up by the various receiving stations being relayed to headquarters by wire line or over radio relay links using other frequencies. This constitutes a special-type large-scale diversity receiving system. In state-wide police systems, several transmitting stations are also usually required.

To avoid interference between police systems in various cities, the power transmitted by the headquarters equipment is generally limited, so that, with small antennas on the cars, high sensitivity in the receiver is required.

A vertical antenna is generally used, mounted either at the rear of the car or in the center of the top. The latter position has the advantage of better omnidirectional

characteristics.[1] Mounting at the back has the disadvantage that the antenna is most sensitive toward the rear.

169. Mobile Radiotelephone. Receivers used in the mobile telephone service are very similar to police equipment except that a handset and a telephone bell are generally provided; also selective calling is usually employed so that the bell rings only in the desired vehicle. Connections may be made to the general wire telephone network of the country, and use of the equipment on the vehicle is practically like the use of an ordinary phone with the exception that a press-to-talk button must be held down while speaking and released while listening. A large number of cars have the same pair of transmitting and receiving frequencies. On account of this "party line" type of operation, it is necessary for the telephone user in the car to listen to see if the facilities are in use before making a call.

Frequency assignments in the band from 30 to 44 Mc have been made for highway mobile telephone, and assignments in the band from 152 to 162 Mc for urban mobile telephone. One frequency for station to vehicle and another for vehicle to station are assigned and together are said to constitute a "channel" for this service. The method of transmission is phase modulation.

The requirements for marine radiotelephony, such as in coastal waters, are much like those in land mobile service with the exception that greater distances may require more powerful transmitters.[2]

170. Selective Ringing. For the purpose of ringing only the desired phone in the mobile service, two types of selective equipment are available. In one type each digit of the called number is represented by a group of the proper number of pulses, and the receiver can be said to operate by counting the pulses in the various groups. In the other type each digit is represented by a particular frequency, or "tone," or a combination of tones. In this case the receiver has filters for identifying the transmitted digits. When the particular installation is being called, the presence of the right digits is recognized by the equipment and the bell is automatically rung, or in industrial or police systems, a loud-speaker may be actuated, a light turned on, or a horn sounded.

An EIA standard[3] provides a definition of the sensitivity of a selective signaling system as the lowest carrier level (determined as in a normal receiver-sensitivity measurement) at which positive operation of the selector is obtained. The corresponding signal-to-noise ratio may then be obtained, keeping the same carrier level, by the following steps: (1) remove the calling modulation at the signal generator; (2) measure the noise output from the receiver; (3) apply 1,000-cps 100 per cent modulation and measure the receiver output; (4) compute the ratio of the outputs in steps 3 and 2, which is the measured signal-to-noise ratio. The result, to comply with the standard, must not be greater than 10 db.

The sensitivity of the selector itself, as distinguished from the entire receiver, is defined as the minimum power input of calling tone which affords positive operation. For this test the selector is connected directly to the tone generator through an impedance-matching element.

Regarding temperature and humidity exposure, the EIA standard requires that neither of the following conditions shall cause harm to the equipment or failure of operation: (1) temperatures from −30 to +60°C at 50 per cent relative humidity, and (2) humidity of 90 per cent and temperature of 50°C.

RAILROAD RECEIVERS

Radio equipment is used in railroad service in the following ways: (1) two-way radiotelephone for dispatching use, especially in freight yards and to a growing extent in main-line operation,[4] (2) receiver operation for the reception of broadcast programs

for the entertainment of passengers, and (3) passenger telephone service enabling calls to be made to and from any phone in the regular land telephone network.

171. Dispatching Service.[1] Frequency assignments in the region from 158 to 162 Mc have been made for the operation of railroad dispatching telephone service. Vertical polarization and phase modulation are used.

In main-line freight service, equipment can be provided in both engine and caboose, affording time-saving communication between the two ends of the train. As an example of main-line operation, a 160-Mc 884-mile installation on the Erie Railroad used 50 base stations, or an average of 18 miles between base stations, the spacing being closer in hilly country. Towers 63 ft high with transmitters of 15 to 20 watts gave at least 5 μv at the receivers.

Flexible mounting of radio equipment is needed in railroad installations, whereas in automotive service it is generally not provided. Larger audio outputs, in the range from 4 to 10 watts, are needed in railroad service because of the high ambient noise.

The v-h-f dispatching service is often called "space radio" to distinguish it from systems having an inductive characteristic, which are taken up in the next paragraph.

172. L-f Inductive and Other Dispatching Services. Guided radio (*i.e.*, wired wireless) systems utilizing the rails and especially the normal wayside telegraph and telephone wires to propagate the waves offer the advantage of greater distance than obtainable with v-h-f operation. Distances as great as 50 to 100 miles between a wayside station and trains are typical.

These systems generally operate on frequencies between 50 and 200 kc and use frequency or phase modulation with a value of approximately unity for the modulation index.

In extended railroad yards an inductive system can be used for the remote control of an additional v-h-f transmitter-receiver. In one design[2] a carrier of 189 kc was used with a deviation of ±4 kc. The distance between the main and the satellite stations was 12 miles. The receiver was a t-r-f type requiring 10 μv to saturate, under which condition it delivered an output of 5 watts; the band width at 50 db was 20 kc and at 70 db was 26 kc.

A railroad dispatching system operating at 2,660 Mc[3] has been reported to give good results. The receiver in this equipment employs a crystal mixer followed by a 7-Mc i-f amplifier having four regular stages, followed by two limiter stages. The i-f band width at 6 db is 300 kc. A special vertical antenna array of biconical parabolic reflectors was designed for this service.

At the opposite extreme in the frequency spectrum is the unit train communication system of the Union Switch and Signal Company.[4] This is an a-m system in which the transmitted signal is a single upper side band of a suppressed carrier such as 5,700 cps. This signal at very low voltage and high current is fed conductively into the rails and picked up inductively from the rails. If paralleling telegraph or phone wires on the right of way are present, distances up to 10 miles can be obtained between trains and distances up to 100 miles between fixed stations and trains. The receiver in this system has two stages which amplify the received single side band and have a.v.c. A push-pull mixer, a peak limiter, and audio amplifiers are also provided.

173. Broadcast Reception on Passenger Trains. Conventional home receivers have long been used in limited numbers on railroads for the reception of programs from standard m-f broadcast stations, the special provisions of such installations generally being limited to suitable antenna and power-supply arrangements. Recently special designs for this service have been made with very good a.v.c., low spurious responses, auxiliary tape sources of music, etc.[5]

174. Telephone Service on Trains. Telephone calls from passengers on railroad trains are handled by the urban and highway mobile facilities, the equipment being similar except for refinements which eliminate the necessity for the railroad user to operate a push-to-talk switch.[1]

MARINE, AMATEUR, AND POINT-TO-POINT RECEIVERS

Receivers designed for use in marine, amateur, and point-to-point service are often called "communication receivers"[2] to distinguish them from broadcast receivers. They differ markedly from broadcast sets in various respects. The general quality of construction is superior, particularly with regard to the use of longer-lived components and to the frequent provision of increased selectivity for reception in the presence of heavy interference. An outdoor antenna rather than a loop antenna is used. Various special features and numerous controls are provided. The housing is generally a functional metal cabinet. In point-to-point receivers, special features and individual design for the particular service may be extensive.

175. Marine Receivers.[3] The severe climatic conditions encountered in tropical waters make it necessary for marine receivers to utilize parts treated with special impregnating agents. In addition, a high degree of general reliability is required, as well as accessibility in case repairs are needed.

Legal requirements applicable to shipboard radio equipment are given in an FCC publication.[4] Large vessels must have separate main and emergency radiotelegraph receivers with separate antennas. Each of these receivers must be capable of receiving c-w and i-c-w telegraph from 100 to 200 kc and from 485 to 515 kc for signal inputs of 100 μv or more. For radiotelephone reception a receiver is required for 1,600 to 3,500 kc with a sensitivity of 50 μv in terms of the more difficult of the two requirements of (1) 0.05-watt output, or (2) 6-db signal-to-noise ratio. Other requirements apply to vessels subject to the Great Lakes Agreement and to equipment for lifeboat use.

Complete assemblies of transmitters and receivers of suitable types are available for shipboard installations.[5]

Another type of marine equipment for ocean-going service is available to provide two-way telephone service at frequencies from 2 to 12 Mc, and especially for the range from 2 to 3 Mc. Except for the use of a.m. and the larger and heavier construction, equipment of this type is similar to that provided for the mobile telephone service. Equipments in this service often include preset tuning arrangements providing a choice of six or ten frequencies with facilities to change the tuning of both transmitter and receiver simultaneously. A push-to-talk button is provided, or a voice-operated relay may perform this function automatically. Selective ringing equipment is available as an additional feature.

There is a trend toward the use of the suppressed-carrier single-side-band method in marine radiotelephone service[6] (see Sec. 152). The intelligibility is satisfactory if the restored carrier is within about 150 cps of the correct value, but for naturalness in the reproduction the difference should be less than about 40 cycles. Receivers for single-side-band service can employ a mechanical i-f coupling system (Sec. 74), which offers adequate band width near resonance plus extreme skirt selectivity.

Marine service does not normally afford sufficient room for useful employment of space diversity reception but can be benefited by the use of transmitting diversity,[1] *i.e.*, the use of two shore transmitters simultaneously sending the same message to the one shipboard antenna and receiver, as discussed in Sec. 193.

Marine receivers arranged for auto-alarm service at 500 kc are treated in Sec. 187. Receivers for direction finding in marine and other services are discussed in Secs. 184 to 186.

176. Amateur Receivers.[2] The manufactured sets offered for amateur service average about 12 tubes and provide various special features. A tuned r-f stage is generally included, to give improved image and i-f rejections and signal-to-noise ratio. A band-spread knob and dial are provided and permit band-spread operation at any point in the frequency range of the set, or in some designs in the amateur bands only. A switch to disable the a.v.c. and one to start a beat-frequency oscillator adapt the set for the reception of c-w telegraph signals.

The crowded conditions on the amateur bands make high selectivity a prime requirement.[3] For this reason, the amateur type of receiver includes in the i-f amplifier a filter having a quartz crystal as one element. The usual i.f. for an amateur receiver is 455 kc, so that this is the natural frequency of the crystal. The very sharp mechanical resonance of this crystal permits band widths as small as 200 cycles to be obtained, thus permitting the reception of telegraph signals through very severe interference. This very sharp selectivity has led to the name "single-signal" receiver. A selectivity control is provided to permit various greater band widths so that phone messages may be received with the best quality permitted by the prevailing conditions.

A noise limiter is generally found in the amateur receiver and is useful for reducing ignition interference.

177. Point-to-point Receivers. The particular requirements often existing in point-to-point service have led to many special receiver designs, some of which are very elaborate. The use of diversity antenna systems is found in this service (see Sec. 193).[4]

An outstanding case of point-to-point receiver design is the transoceanic radiotelephone equipment used by the Bell System.[5] The receiver in this equipment operates on any frequency from 4 to 22 Mc and provides as many as four one-way voice channels in a radio band having a total width of 12 kc. Each channel is of commercial telephone quality with a width of about 3,000 cycles. An elaborate form of single-side-band operation (Sec. 152) is used.

These channels are obtained as follows: (1) a side band somewhat removed from the carrier on one side furnishes one channel; (2) a similar displaced side band on the other side of the carrier furnishes the second channel; and (3) a third channel is "straddled" across the carrier, or the third and fourth channels are placed near the carrier on the two sides.

All channels of such transoceanic telephone services normally utilize the standard commercial privacy equipment (see also Sec. 200), which divides the voice range of 250 to

3,000 cps into five equal 550-cps portions and interchanges these, with or without inversion, making a change in the arrangements every 20 sec.

To receive and separate a transmission of this kind is the function of a receiver having various special features. The design is a double superheterodyne with a first i.f. of 2,800 or 2,900 kc and a second i.f. of 100 kc. The transmission employs carrier of reduced amplitude. The receiver can therefore be operated to produce and use reconditioned carrier obtained from the incoming signal, or it can produce and use a standard 100-kc frequency as a resupplied carrier. Crystal filters operating in the neighborhood of 100 kc provide sufficient selectivity for separation of the carrier and the various desired side bands. The receiver includes a mechanical type of a.f.c. which operates on the first heterodyne oscillator so as to maintain the frequency of the 100-kc carrier in the second i-f amplifier.

Studies of long-distance ionospheric (25 to 60 Mc) communication by Murray G. Crosby[1] led to the conclusion that "the trend in improving the difficult transmission conditions of long-range communication has been toward the angle-modulated frequency shift system in the case of telegraphy, towards single-sideband operation in the case of a band-type of modulation, and towards improved applications of exalted-carrier and single-sideband diversity receiving systems."

One of the severe requirements applying to both transmitter and receiver in multiplex radiotelephone systems is to hold intermodulation to a sufficiently low level so that the signal in one channel will not cause excessive noise in the other channels. A 150-Mc system using f.m. with ± 15 kc maximum deviation, providing the equivalent of four phone channels, has an intermodulation between the two test tones which is 50 db down, a value considerably better than that of f-m mobile service or single-channel point-to-point phone service.[2]

One of the features needed for receivers in radio extensions of land telephone service is CODAN (carrier-operated device anti-noise).[3] This is a squelch system (Sec. 93) serving to disable the receiver when the person at the other end of the connection is not talking.

Another special feature often forming a part of the receiver is the expanding portion of a compandor (Sec. 123) to restore the volume range after the compression performed at the transmitter. Available companding equipment gives an average noise reduction of 22 db.[4]

Other devices used in such radiotelephone service and having an influence on receiver design are the VOGAD (voice-operated gain-adjusting device), which can be called an "audio automatic volume control," and the VODAS (voice-operated device anti-singing), which is a system of voice-operated relays to disable the unused direction of transmission at each instant so as to prevent oscillation or objectionable echoes.

An outstanding type of point-to-point reception is in *scatter-propagation* systems,[5] which are characterized by: (1) use of frequencies in the v-h-f, u-h-f, and s-h-f bands (which are normally limited to horizon distances); (2) operation, nevertheless, at distances very much beyond horizon values; (3) use of high transmitting power; (4) use of large directive antennas at both transmitter and receiver; and (5) use of more than one receiving antenna in a receiver-diversity system. Under these circumstances the receiver should be designed for low noise factor and good diversity operation. At frequencies of 100, 200, and 400 Mc noise factors of 3, 3.5, and 4.5 db, respectively, are obtainable, and at frequencies above 900 or 1,000 Mc, where an r-f stage is no benefit, a value of about 8 db is obtainable.

178. U-h-f and S-h-f Relay Receivers. A relay system operating at 2,000 Mc has been installed by General Electric between New York and Schenectady.[6] This

[6] Deerhake, F. M., 2000-Mc Television Program Chain, *Electronics*, February, 1948, p. 94.

system operates with f.m. and a maximum deviation of ±7 Mc. The receiver resembles those in radar practice and has a 1N21B crystal mixer, an SRL-7A klystron superheterodyne oscillator, and an i-f amplifier operating at 100 Mc. The i-f amplifier includes three triplets, each consisting of three stages. Each triplet is stagger-tuned at 92, 100, and 108 Mc. In this way a band width of 16 Mc is obtained. These three triplets are followed by a two-stage limiter, which is followed by a discriminator for detection of the video signals, the purpose of the relay system being to transmit television programs.

A 4,000-Mc relay system for television and multiplex telephone service has been designed by the Bell System and widely installed. The receivers in this system utilize a crystal for conversion to an i.f. of 70 Mc. No r-f amplification is used in the receivers. The transmitters use the planar-electrode 416-B triode, which in other applications (Sec. 156) has been found suitable for small-signal amplification at frequencies from 60 to 4,000 Mc.

Point-to-point equipment for television pickup service at 7,000 Mc has been designed by RCA.[1] This operates with f.m. The receiver is divided into two parts, the first of which is mounted directly behind the parabolic "dish" which constitutes the receiving antenna. This part of the receiver includes a crystal mixer, a 2K26 klystron oscillator, and four i-f stages operating at 120 Mc. The band width is 20 Mc. A.f.c. with a d-c amplifier is provided, acting on the reflex electrode of the klystron. The second unit of the receiver furnishes additional i-f amplification, as well as discriminators for the signal circuit and for the a-f-c operation. The i.f. corresponding to the peaks of the television synchronizing signal is held by means of the a.f.c. to an accuracy of ±1 Mc regardless of the picture content.

MILITARY AND NAVAL RECEIVERS

Special attention to reliability despite severe conditions of temperature, humidity, mechanical shock, and vibration is necessary in the design of military and naval radio equipment. In addition, in case the apparatus is for use in aircraft, it must operate at greatly reduced air pressure or be housed in an airtight case raising problems of heat dissipation. Numerous specifications have been prepared giving details of these various requirements, and compliance with such specifications is required according to the contracts under which equipment is purchased by the Government from manufacturers. Special attention is necessary on the part of the design engineer to ascertain definitely what specifications must be observed and to work out satisfactory designs.

A systematic method of assigning model designations is used in the United States defense services.[2] For example, in the *AN/APR*-3 the *AN* indicates that this is a military equipment, the *A* following the slant line indicates that it is for aircraft installation, the *P* indicates radar (or "pulse") equipment, the *R* indicates the purpose as reception, and the 3 distinguishes from preceding and later assignments of the same letters.

179. Typical Military Requirements. Selected provisions from various specifications will serve to indicate some of the special features required in radio equipment for the defense services. The precise requirements in each case depend on the specifications listed in the contract applicable to the particular equipment, the choice of the particular specifications being made by the Government authorities on the basis of the character and purpose of the equipment and the state of military and radio knowledge at the time.

Temperature. A typical requirement is that operation must be satisfactory for extended periods at any point from −55°C (−67°F) to +55°C (+131°F). Operation at higher temperatures may be required in some cases. Resistance to high humidity is generally required, such as exposure to 100 per cent humidity at a temperature of 50°C (122°F).

[1] Poch, W. C., and J. P. Taylor, Microwave Equipment for Television Relay Service, *Broadcast News*, October, 1946, p. 20.

[2] "Reference Data for Radio Engineers," International Telephone and Telegraph Corp., New York, 1956; see pp. 957–963.

Pressure. For air-borne equipment, operation at a pressure of 3.4 in. Hg, corresponding to an altitude of 50,000 ft, is a representative requirement.

Vibration. Requirements may include the range from 10 to 55 cps with the equipment being tested at a total excursion of 0.06 in. The design of flexible mountings for resisting vibration and shock is quite important.[1]

Shock. Resistance to shock is necessary so that the equipment shall not be readily disabled by the rough landing of aircraft, enemy bombs bursting on the decks of vessels, or other causes. Shock corresponding to an acceleration of 25 g is sometimes stated as a value which must be successfully withstood. Another specification, in dealing with equipment weighing over 250 lb, requires that it be mounted on a table weighing about 2 tons, and that the table then be struck underneath with a 3,000-lb hammer moving at a velocity corresponding to a fall through a height of 9 to 66 in., the value of this equivalent fall varying with the weight and class of the equipment.

Components. Inductors and transformers having laminated-iron cores are subject to severe requirements and must pass tests for temperature rise of the windings in operation, as well as exposure to extreme external temperatures and immersion in successive baths of hot and cold water. The potting compound must not crack at −55°C (−67°F) nor flow at +85°C (+185°F).

Variable capacitors must have a nominal clearance between fixed and moving plates of not less than 0.012 in. and an actual clearance not less than 0.008 in.

Electrolytic capacitors are normally usable only if approved by the Government after a showing by the contractor. In case their use is approved, the plug-in type is preferred but must be provided with means for firmly holding the capacitor in its socket.

Resistance to corrosion must include the ability to withstand exposure to a salt sea atmosphere. In the case of steel, phosphate treatment is generally acceptable. Another acceptable finish on steel is a cadmium plating of 0.0005 in. thickness followed by either a dichromate treatment or lacquering. Aluminum can be treated by (1) anodizing, (2) a caustic dip and lacquer, or (3) sandblast and lacquer.

Major improvements have been made in components[2] to meet the military needs for smaller size, improved reliability, ability to withstand higher temperatures,[3] and other properties.

The transistor offers various advantages for military equipment. A study of its application in air-borne apparatus led to the recommendation of 18 volts as standard d-c power supply for Air Force transistor equipments.[4]

Fungus. The war in the Pacific demonstrated that resistance to the growth of fungus[5] is one of the most important requirements for military equipment to be operated in the tropics. It is necessary to avoid the use of fungus-nutrient material as far as possible and, where this is impossible, to treat with a fungicide. The thickness of the fungicide spray after drying should be 0.002 in.

Radiation. Receiver radiation must be less than 400 $\mu\mu$w according to the usual naval requirement.[6]

Soldering. The soldering of wires must normally follow a secure mechanical attachment, so that the soldering is not depended on for mechanical strength. The use of excessive solder is not acceptable. Not over three wires may be attached to one lug, but multiple lugs may be used to whatever extent necessary.

Preferred Circuits. A study of many circuits for the most frequent functions was made by the National Bureau of Standards and led to the recommendation of 32 as preferred types for defense equipment.[7] These include power supplies, amplifiers, voltage regulators, and other types.

Exposure to Severe Cold. Expeditions and tests in cold climates[1] have shown that under practical conditions radio, radar, and other electronic equipment are useful, but that the available models were subject to certain limitations. At one location in the Antarctic, situated on a thickness of several hundred feet of ice, local interference due to ignition and commutator noise was severe because the thickness of ice prevented the use of a ground connection. Another difficulty encountered was the unloading and moving into position of heavy diesel-engine generators for GCA systems. Other tests in severe weather showed that the handicap of extreme cold greatly reduces the efficiency with which personnel are able to install, calibrate, operate, maintain, and repair electronic apparatus.

180. Reliability of Military Equipment. The increasing amount and complexity of electronic apparatus in military and naval craft, like a chain dependent on more and more links, has often resulted in poor reliability despite compliance with the various component and system specifications. On this account special emphasis has been placed on achieving improved reliability,[2] and extensive studies and programs of action have been initiated.

While all components are important for reliability, a special need for improved quality and proper applications has been felt with regard to tubes.[3] Receiver designers should avoid such faults as dependence on tube characteristics which are uncontrolled in production, inadequate equipment operation during the latter part of normal tube life, and excessive envelope temperature. The engineering literature, as well as the applicable specifications, should be carefully followed to obtain the desired reliability (see Fig. 39).

FIG. 39. Performance vs. reliability for various classes of engineering design. (*From Leubbert, Proc. IRE, April,* 1956.)

181. Receivers for Identification and Beacon Service. Identification and beacon systems[4] include (1) an interrogator-responsor (also called an "I-R," or "challenger") which initiates the operation, and (2) a transpondor (also called a "replier" or "respondor"), which automatically answers the interrogation. An I-R is a transmitter-receiver, and a transpondor is a receiver-transmitter. Identification systems operate as accessories to radar. After the radar has shown the presence of a distant plane or vessel, the identification equipment enables the friendly character of the distant craft to be checked. All friendly craft must therefore carry transpondors. In addition, craft that are expected to make attacks on the enemy must be equipped with

interrogator-responsors so as to make a check of identity before proceeding with an attack. Normally therefore interrogator-responsors are furnished in one or more of the craft in any attacking group.

The receivers of I-Rs are superheterodynes very similar to those in radar practice. The receivers of transpondors may be either superheterodynes or superregenerators with AGS.

A radar beacon system is much like an identification system. The moving craft sends out the interrogation and the beacon returns the reply; *i.e.*, the I-R is on the craft and the transpondor is at the known point where it acts as the beacon. The craft learns its location by (1) knowing the identity of the beacon from the special coding of the reply, (2) observing the location of the reply on the radar scope, and (3) taking advantage of the fact that, starting with the known location of the beacon, the reverse bearing and the same distance determine the point on the map where the craft is located.

The Brunn method of increasing the effective selectivity of a pulse receiver, described in Sec. 163, can be used advantageously in beacon service.

182. Countermeasure Receivers.[1] To reduce the value of radio and radar to the enemy, it may be necessary to (1) ascertain the frequency of the transmission and (2) radiate an interfering signal of sufficient strength and suitable modulation to prevent the enemy from realizing any benefit from his efforts. Special search receivers are required for the first of these functions. Another aspect of countermeasure-receiving technique is the use of two or more direction finders so as to ascertain the location of an enemy transmitter.

Search receivers for finding enemy radar signals[2] were developed during the Second World War, the designs being superheterodynes covering the range from 25 to 10,000 Mc. Butterfly tuners and acorn tubes were used up to about 1,000 Mc with an i-f amplifier of 3 to 4 Mc band width centered at 30 Mc. Image rejection was over 40 db at the lower frequency and over 10 db at 1,000 Mc. From 1,000 to 10,000 Mc, concentric-line oscillators with reflex klystrons were used. A 200-Mc i-f amplifier having a band width of 20 Mc at the peak and 24.5 Mc at 6 db, used with a two-cavity preselector, gave image rejections of 40 to 60 db. Reflector voltages were about 300 at the lower end of the band, increasing to 1,250 at the upper end. These equipments were air-borne and, with associated jammers, greatly reduced the effectiveness of German antiaircraft radar fire control.

Wartime countermeasure research and development centered at the Harvard Radio Research Laboratory, and the general engineering findings of this work are available in the literature.[3]

For search receivers in the centimetric band (s-h-f), it may be desired to have a large value of r-f band width so as to receive any signal in a wide range of frequencies without change of the r-f or oscillator tuning. One design approach for this purpose[4] employs simultaneously a group of heterodyne frequencies with an i-f amplifier having a substantial band width such as one-half the spacing of the oscillator components. Traveling-wave tubes may be used in such an i-f amplifier. This type of search receiver is reported to have sensitivity comparable with that of normal superheterodynes and band width comparable with that of crystal-video designs.

Panoramic equipment is of special interest in search receivers and is described below.

183. Antijamming Features in Receivers.[5] As a counter-countermeasure it is essential to design military receivers to be as immune as possible to enemy jamming.

[1] A nontechnical account of radar countermeasures is given in James Phinney Baxter, III, "Scientists against Time," Little, Brown, 1947; see pp. 158–169.

[2] Radar Countermeasures, *Electronics*, January, 1946, p. 92. Sinclair, D. B., Search Receivers for Radar Countermeasures, *Gen. Radio Experimenter*, March, 1947, p. 1. Villard, O. G., Jr., Radar Countermeasures: The Science of Immobilizing Enemy Radar, *Proc. Radio Club of America*, March, 1946, p. 7.

[3] Staff of Radio Research Laboratory, Harvard University, "Very High Frequency Techniques," McGraw-Hill, 1947.

[4] Cohn, M., and W. C. King, A Sideband-mixing Superheterodyne Receiver, *Proc. IRE*, **44**, 1595, November, 1956.

[5] Henney, K., ed., *et al.*, "Reliability Factors for Ground Electronic Equipment," McGraw-Hill, 1956; see pp. 9-12 and 9-13 on antijamming and anticlutter circuits.

The first antijamming feature is naturally against unmodulated c-w interference. Such immunity is obtainable to a good degree in a radar receiver by changing from a d-c coupling to a capacitance-resistance type between the detector and the first video stage. This prevents the first video stage being biased beyond cutoff by the rectified jamming signal.[1]

Certain types of modulation on the interfering signal can be much reduced by switching in a short-time-constant coupling (a differentiator) between the detector and the first video stage. For example, the time constant can be reduced to only 1 μsec, assuming that the desired signal consists of short pulses.

If the interference overloads the i-f amplifier at the times of high a.m. of the interference, the condition can be improved by fast a.v.c., also called "instantaneous automatic gain control" (IAGC) or "back bias."[2] Such controls can be applied to one or more of the last i-f amplifier stages.

The IAGC circuit is also useful in reducing "clutter" on the radar scope, such as due to echoes from land, sea, or clouds. Another means for reducing clutter is sensitivity-time-control (also called "STC" and "GTC"), which reduces the receiver sensitivity immediately after each transmitter pulse and then rapidly increases the sensitivity as more distant echoes arrive.

The a.f.c. of a radar receiver would be subject to jamming by c-w interference if a separate a-f-c crystal mixer were not provided.[3] By including such a separate crystal, it can be arranged to deliver the difference between the transmitter frequency and the local oscillator, so that the a.f.c. is unaffected by returning echoes or incoming interference.

Good antijamming properties and other merits have been found for a system of a-m transmission and reception in which (1) the carrier component is suppressed, (2) the two side bands are radiated, and (3) synchronous or coherent detection is employed, the reinserted carrier being developed from the two side bands.[4]

DIRECTION FINDERS

The directive properties of loops and other types of antennas make possible the design of direction finders[5] for the various portions of the radio spectrum. A direction finder is a radio receiver with a rotatable antenna or other means for determining the direction of arrival of a wave from a distant transmitter. Many instruments indicate first the direction of the infinite straight line passing through the transmitter and the direction finder, after which some further manipulation by the user is required to ascertain which end of the line is toward the transmitter, *i.e.*, to remove the 180-deg ambiguity. With an "automatic direction finder" or ADF, the needle of a dial shows the direction without ambiguity. Other types show the direction on a cathode-ray tube and are constantly sweeping the horizon so that very brief transmissions can be seen.

Direction finders with scope indicators operating in and below the v-l-f region have been found useful for locating storms over ocean areas.[6] One direction finder for this service has a tuning range from 3.6 to 17.5 kc.

184. Typical Marine Direction Finders.[1] The law requires certain classes of vessels to be equipped with direction finders for the range from 285 to 515 kc. This is sufficient to operate on the marine beacons at 285 to 315 kc, the ship-to-ship compass frequency of 375 kc, and the international distress frequency of 500 kc.

The typical marine direction finder has a shielded loop antenna, a simple antenna for sense (180 deg ambiguity) determination, an r-f stage for each half of the loop (the center of the loop being grounded), a highly selective receiver, and headphones. The receiver is generally a superheterodyne of 6 or 8 tubes, and 175 kc is a typical i.f. Sensitivity values are typically 80 to 100 db below 1 volt per m (100 to 10 μv per m) for 6 mw out at 300 kc. The sharp selectivity can be seen from the representative 300-kc band widths of 6 kc at 20 db, 10 kc at 40 db, and 14 kc at 60 db.

Loop antennas for the range of 80 to 200 kc can be made smaller or more sensitive by the use of ferrite cores, and studies of rod and tube shapes,[2] and also spheroidal shapes,[3] of cores have been made.

185. Automatic Direction Finders.[4] In aircraft navigation, bearings with a direction finder are wanted on a rapid and continuously indicating basis. This need is satisfied by the ADF, which has come to be a standard type of instrument. These equipments furnish nonambiguous readings. A servo system automatically keeps the loop and an indicating needle oriented for the desired station as the plane proceeds. At least one dual type is available in which an additional antenna and receiver are provided to operate a second needle of the indicator, so that the bearings of two stations are continuously shown. The frequency coverage of ADFs is usually from 150 to 1,700 kc, and the i.f. about 112 kc. The sensitivity is about 94 db below 1 volt per m (20 μv per m). The loop antennas for ADFs are usually shielded and also housed in a specially coated radome to reduce precipitation static.

An automatic marine-type direction finder made by Raytheon for the Coast Guard[5] uses a 60-cycle switching frequency for the automatic operation. The receiver accommodates the frequency ranges 275 to 510 and 2,000 to 3,500 kc, and has an i.f. of 912 kc. The higher-frequency band includes much of the ship-shore radiotelephone service and also the international radiotelephone distress frequency of 2,182 kc.

186. Other Types. Various designs for quickly taking bearings in the h-f (3 to 30 Mc) spectrum have been made.[6] These included scope presentation of the polar type, the DF station being represented at the center and an indication in any direction showing instantly the bearing of the distant transmitter.

These equipments have two fixed antenna systems oriented at right angles to each other and connected to the two primaries of a special transformer called a goniometer. An accurate right-angle relation between the two primaries is established in the construction of the goniometer. The secondary winding rotates in the field of the two primaries and therefore picks up signal in the same way as a loop antenna rotating in space. A motor spins the secondary at high speed and also controls the scanning of the scope.

The Adcock type of antenna system, consisting only of vertical elements without the horizontal portions of the loop antenna, has desirable properties for d-f use and is

extensively employed. Careful studies of the remaining errors in bearings taken with an Adcock system are available in the literature.[1]

An international distress frequency for lifeboats and other survival craft has been established at 8,364 kc, whence any direction finder for this general spectrum region should include this frequency.

The use of height diversity, *i.e.*, two antennas at different heights, affords improved direction-finder operation in the range of 225 to 400 Mc.[2]

Land d-f antenna systems utilizing the Doppler principle for service between 0.8 and 30 Mc offer improved accuracy.[3] The antenna equipment consists of two or three dozen individual omnidirectional antennas arranged in a large circle, each with a cable connecting to a rotating pickup switch located at the center of the circle. In effect, a single antenna is carried around the circle at the angular rate of the switch. The frequency received is normal when the antennas nearest the transmitter are effective, and likewise for those farthest away; but between these points the frequency is increased on one side and decreased on the other side because of the Doppler effect. With a switching rate of 42 cps, a circle diameter of 150 ft, and an incoming signal of 1.5 Mc, the maximum frequency deviation to one side is 30 cps.

Lobe switching, as used in radar practice, is an additional means of direction finding.[4] For this purpose the directional antenna is varied in some manner so as to make a slight change in the direction of its greatest sensitivity; at the same time the indicating means is also commutated so as to obtain an additional indication. With these facilities it is possible to direct the antenna approximately toward a "target" and then accurately adjust the direction for equality of the signal from the two lobes.

AUTOMATIC ALARM RECEIVERS

An interesting type of receiver[5] is used on vessels and at shore stations to receive automatically the international distress signal at 500 kc and sound alarm bells. The international signal for this purpose, established at the Madrid Telecommunications Conference of 1932, is a succession of dashes, each lasting 4 sec, separated by spaces of 1 sec.

187. Autoalarm Specifications. The FCC requires these receivers to operate at any frequency between 492 and 508 kc with a 30 per cent modulated signal of 100 μv. Assuming the antenna to have an effective height of 5 m, this corresponds to a signal strength of 20 μv per m. A warning must be given for various defective conditions, such as a burned-out filament. Means for checking with a local test signal must be provided. The equipment must withstand various conditions of temperature, vibration, etc.

Recent FCC regulations applicable in type tests on new autoalarm designs after the effective date of the Safety Convention (London) require that the alarm shall operate upon the receipt of "either three or four consecutive dashes when the dashes vary in length from 3.5 to as near 6 seconds as possible and the spaces vary in length between 1.5 seconds and the lowest practicable value, preferably not greater than 10 milliseconds." These provisions and also the requirement of special automatic gain characteristics are for the purpose of increasing the effectiveness of the instrument in the presence of heavy atmospherics and interference.

RECEIVERS FOR USE IN AIRCRAFT

188. General Requirements. The design of receivers for use in aircraft requires special attention to obtain light weight, suitable housing, resistance to vibration, adaptability to aircraft antennas, operation with available power sources, and resistance to interference conditions.[1] In addition, remote control is often required.

189. Interference Effects.[2] The ignition system of an airplane motor produces vigorous electrical effects characterized by steep wave forms which contain frequency components throughout a very wide range. These would induce an overwhelming amount of interference into any radio antenna on the plane unless they were confined by thorough shielding of the entire ignition system. In addition, shielding or filtering, or both, of most of the other wiring on the plane is required to avoid radio interference. It is especially necessary to filter leads which are connected to vibrating regulator contacts or to d-c motors. Small r-f filters are advisable in the receiver in series with each power-supply wire from outside, and also in series with external leads for audio connections, remote control, and other purposes.

Another essential element for radio reception in planes is that the various metal parts of the craft, especially moving parts, and its accessories must be firmly bonded together, as by the use of heavy copper braid.

When flying is undertaken through snow, rain, ice crystals, or dust, especially at the higher speeds, precipitation static is encountered. This is due chiefly to neutral particles striking the plane, where they are ionized by friction, furnish a high electrostatic potential to the plane, and thus cause the plane to discharge into the surrounding air and produce radio interference. The potential of the plane may rise to a quarter of a million volts or more in severe cases. The discharge which occurs is corona, sometimes known as "Saint Elmo's fire." The effect on radio reception is worst if such discharge takes place from the antenna itself, but may still be severe if the discharge occurs only from the plane itself.

An extensive investigation of precipitation static was conducted by the Naval Research Laboratory, the Aircraft Radio Laboratory, and the University of Minnesota[3] using d-c potentials as high as 1,200,000 volts. The results of this and other work have been embodied in a report of the Radio Technical Commission for Aeronautics.[4]

190. Loop Antennas for Aircraft Reception.[5] The directional properties of the loop antenna and its independence of the electric field when shielded make it a valuable

type of aircraft antenna for the lower frequency ranges. Sizes up to a maximum diameter of about 12 in. have been used. Shielding is always provided, located either near the wires or as part of a streamlined housing. In case the shielding is close to the wires of the loop, the radome should be slightly conductive. Loops of 4 to 20 turns are generally used and are called "low-impedance" in distinction to designs with a greater number of turns which have been used to a limited extent. The design of the loop can be solenoidal (all turns have the same radius) or pancake (meaning that there is a gradually changing radius with all the turns in the same plane). Composite designs with both solenoidal and pancake features can be used.

Aircraft loops with iron cores have been extensively used in Europe. This design is reported to offer the advantages of smaller size and suitability for placing nearer the metal fuselage of the plane.

191. Use of 28-volt Plate Supply.[1] The 24-volt airplane battery furnishes a supply averaging about 28 volts while being charged. This is sufficient potential for the plate supply of certain tubes specially designed for the purpose. Care to avoid difficulties due to improper grid current is necessary in the operation of tubes at this low plate voltage.

The 28D7 can be operated as a low-power high-voltage supply by the provision of an oscillator circuit and a rectifier. Outputs up to 725 mw are obtainable at potentials of 50 to 250 volts, and smaller outputs are obtainable up to 500 or 600 volts. The frequency of oscillation can be located between 4 and 10 Mc. As the rectifier, the 14A4 tube can be used up to 300 volts, and the 28Z5 for higher voltages. By this use of the 28D7, limited amounts of high-voltage current can be obtained while still utilizing only a 28-volt source of power.

PANORAMIC RECEIVERS

A panoramic receiver[2] has an oscilloscope tube and suitable circuits to show the intensity of the signals available at the antenna over a frequency spectrum extending considerably above and below the frequency being received. This feature is obtained by means of an auxiliary channel which has amplifiers, a mixer, a swept oscillator, and the scope. The coupling into the auxiliary channel is from the modulator of the receiver and is made through a broad-band circuit so that signals of higher and lower frequency than the one being received will come through and appear with uniform strength on the scope.

192. Panoramic Details. The mixer of the auxiliary channel produces a new i.f. which then goes into a sharply tuned amplifier, the output of which is applied to the vertical plates of the scope. A sweep oscillator produces a saw-tooth output which is applied to the horizontal plates of the scope for scanning. The saw-tooth wave also drives a reactance tube so as to vary the frequency for which the auxiliary channel is sensitive. In this way the spectrum of interest is scanned, the frequency usually being 30 cps so as to produce a steady pattern on the scope. The horizontal axis shows the frequency at any point. Where a signal exists, an upward deflection or "pip" will be seen. If, for example, five transmissions in the frequency range of interest are taking place, five corresponding pips will appear. Furthermore, from the shape and time variation of each pip, the experienced observer can ascertain various information regarding the type of modulation and general character of the signal.

The panoramic feature is useful in communications to show frequency spaces not in use at the particular moment and therefore available for use, thus avoiding interference in crowded bands.

In military service, panoramic displays are widely used for quickly detecting hostile

IRE*, **42**, 948, June, 1954.

transmissions. Also in radio operations with other friendly forces panoramic displays permit one operator to guard a much wider frequency range and respond to incoming signals more quickly.

The panoramic principle has often been applied in the form of a separate accessory or adapter to be used with a conventional receiver. One such adapter, called a "panadapter,"[1] is made in various types including one which is suitable for use with any receiver having an i.f. between 450 and 470 kc.

The broad-band coupling, which receives signals from the mixer of the receiver and serves as the input element of the panadapter, is given a double-peaked characteristic to offset the r-f selectivity of the receiver and give more uniform heights for signals of the same strength at various frequencies represented on the scope presentation.

Ferrite inductors affording a 2.25:1 inductance range under d-c control have been used in a panoramic receiver covering the frequency range from 100 to 150 Mc.[2] In this design seven such inductors have their d-c windings in series, and thus tune the oscillator and six signal-frequency couplings in the three-stage r-f amplifier. Beyond this point the circuit is a double superheterodyne with i.f.s of 30 and 3 Mc.

DIVERSITY RECEIVERS

Experience has shown that, when a signal fades at an antenna, it is usually fairly strong at a distance of 10 to 100 wavelengths away. Diversity receiving systems[3] take advantage of this fact and consist of two or more spaced antennas with special receiving equipment arranged to deliver a single output signal of improved character.

In terms of wavelength the larger separations of diversity antennas, such as 25 to 100 wavelengths, apply to the decimetric (u-h-f) and higher frequency ranges. For the dekametric (h-f) range the best values and the minimum useful values are given in Table 17.

Table 17. Values of Separation of Antennas in Dual-diversity Receiving Systems*

Frequency, Mc	Wavelength, m	Spacing of antennas, center to center, wavelengths	
		Best value	Min useful value
18.9	15.89	20	7
13.7	22	10	4
7.4	40.5	7–10	4

* Ladner, A. W., and C. R. Stoner, "Short Wave Wireless Communication," 5th ed., Wiley, 1950; see pp. 578–581.

193. Diversity Receiver Details. The conventional arrangement of receivers operating in a diversity system provides for each antenna a complete receiver up to the point where the diode detectors are connected to a common load resistor. This resistor has an audio drop across it which for radiotelephone reception is the desired signal. The common load resistor also has a d-c drop which is applied as a-v-c bias to all the receivers. With this arrangement, the d-c potential across the load resistor is determined by the strongest signal present. This is because this potential acts as a back bias on all the diodes and cuts off all of them except the one with the strongest signal. In this way only the strongest signal delivers output, and the noise that would otherwise come in from the other antennas is suppressed. As an alternative, audio mixing

of signals from diversity antennas has been used followed by an audio-derived gain control.[1]

Practical points regarding receiver design for diversity operation evolved during years of experience may be found in the literature.[2]

On important circuits *frequency diversity* may be used in addition to the space diversity which has been considered so far. Frequency diversity merely consists of the transmission of the message simultaneously on more than one carrier frequency. Excellent results using 3 to 8 per cent frequency interval at about 6,000 Mc have been found by H. Magnuski of the Motorola staff and F. H. Willis of the Bell Telephone Laboratories, and Magnuski states that the possibility of using substantially lower powers may well result in spectrum conservation. However, the FCC will authorize frequency diversity only on a factual showing in each case that the required communications cannot practicably be achieved by other means (Paragraph 21.100 of their Rules and Regulations dated September, 1956).

Frequency diversity is almost synonymous with *transmitter diversity*, meaning the use of two or more transmitters to send the given message simultaneously. On shipboard, where the use of receiver diversity is normally impractical, improved service can be furnished by transmitter diversity. This has been found to give better reception of teletype signals, which are very subject to errors from fading.[3]

Somewhat related to diversity methods is the "musa" antenna system developed about 1937,[4] the term being coined from "*M*ultiple-*U*nit *S*teerable *A*ntenna." This consists of a group of rhombic antennas with phasing circuits so as to achieve (1) a high degree of vertical directivity and (2) the ability to control the vertical angle, thus "steering" the antenna. With this antenna system it is possible to favor the path on which the desired signal is arriving and discriminate against other paths. This is therefore a means of combating multipath propagation and its attendant selective fading. The musa has been found to give an improvement in quality for a considerable portion of the time and to afford a substantial improvement in signal-to-noise ratio under various conditions of poor transmission. However, the cost of the musa installation is substantial.

Diversity operation was found useful in the s-h-f range in tests at 4,500 Mc between San Diego and San Francisco.[5] At the receiving end of one of the relay links two parabolic antennas were used, one mounted 25 ft below the other. It was found that the short fades that occurred were not simultaneous at the two antennas. The outputs of the receivers were paralleled after the first video stage. The a-v-c voltages of the two receivers were connected together in the manner already described in this section. This system operated with pulse-time-modulated equipments. The 25-ft separation amounts to 112 wavelengths. The use of antennas spaced in height is called *height diversity*.[6]

The use of diversity is an important element in scatter propagation. Studies of the size for individual antennas and the separation for diversity operation[7] turn upon the distance at which the field strengths can be considered to be independent or uncorrelated. There

is little advantage in making a single receiving antenna larger than this because of the miscellaneous phases of the waves in the outer regions. With respect to diversity, an absence of correlation is desired, so that the separation should amount to at least this much. This distance is called the *diversity distance* or the *correlation distance.* Its value depends on whether the direction of interest is vertical, horizontal to one side, or horizontal in the direction of the ratio path. For the horizontal distance in kilometers normal to the path it is

$$D_h = 6{,}000 \frac{\lambda}{d}$$

where λ = wavelength, km
d = transmitter-receiver distance, km

The vertical diversity distance is

$$D_v = 8{,}000 \frac{\lambda}{d}$$

The horizontal diversity distance in the path direction is

$$D_a = \frac{Dv^2}{2\lambda}$$

Studies have shown that theoretically it is better not to discard the weaker diversity signals, because use can be made of them to improve the over-all signal-to-noise ratio.[1] Such a combining operation can be obtained by paralleling the outputs of all the receivers and having the output impedance of each receiver vary in proportion to the noise-power output of that receiver. In this way a receiver with a poor signal-to-noise ratio (and therefore a high noise level) will have a very high output impedance which will prevent the noise from being delivered to the output.[2]

One additional type of diversity is *polarization diversity,* meaning that the message is received on two antennas, one for horizontal polarization and the other for vertical polarization.[3]

WIDE-BAND RECEIVERS

In services such as television and pulse-type systems, receivers must possess a very much greater band width than required for simple radiotelegraph or radiotelephone operation. For example, band widths up to 4 Mc are necessary in television transmitters, and values up to 10 Mc or more characterize certain pulse transmissions.

194. Gain–Band-width Product and the Band Merit of Tubes. Studies by H. A. Wheeler[4] led to the realization that for the ideal coupling network, there is a maximum value of the product of stage gain and band width. This ideal maximum is

$$Af_w = \frac{g_m}{\pi \sqrt{C_g C_p}}$$

where A = voltage gain between equal impedances
f_w = band width, cps
g_m = transconductance of tube, mhos
C_g = total grid-to-cathode capacitance in circuit, farads
C_p = total plate-to-cathode capacitance, farads

If it is desired to realize a large part of this ideal maximum value, coupling networks of three or four reactances are necessary.

[4] Wheeler, H. A., Wide-band Amplifiers for Television, *Proc. IRE*, 429, July, 1939.

For a simple parallel-resonant circuit as the coupling means, the relation takes the form[1]

$$Af_w = \frac{g_m}{2\pi C}$$

where C is the total of C_p and C_g.

This expression for the maximum gain–band-width product with a simple tuned circuit as the coupling has been used to obtain a figure of merit for comparing various tubes of interest as wide-band amplifiers. The point of view is that with wider and wider band widths, the obtainable gain with the particular tube declines until it reaches unity; *i.e.*, the output is no greater than the input. This makes A unity in the equation, so that it is only necessary to insert the values of g_m and C for the particular tube to compute its band merit. Distributed capacitances, such as those of the coil and wiring, are omitted in this calculation, as they are not properties of the tube. Table 18 gives values of the band merit for several pentode types.

Table 18. Band Merit of Various Pentode Tubes

Tube type	Transconductance, μmhos	Total of input and output capacitances, μμf	Band merit, Mc
6K7	1,600	20	13
1AD4*	1,700	8	36
5902*	4,200	14	48
6AU6WA	5,000	12	70
5749/6BA6W	4,300	11	70
5639*	9,000	17	85
6AG7	11,000	20	88
6AC7	9,000	16	90
5899*	4,500	7.7	94
6AG5	5,100	8.3	98
6AH6	8,000	13	98
5840*	5,000	7.6	105
5654/6AK5W	5,100	6.8	120
5847/404-A	12,500	9.5	210

* Subminiature type.

An essential part of a wide-band receiver is the i-f amplifier. A general treatment of this is given in Sec. 77. Stagger tuning and feedback methods are used to obtain wide-band response.

After detection of the signal, it is usually necessary to amplify it further. In wide-band receivers such an amplifier is usually called a "video amplifier" because the signal is in many cases displayed on a scope as a television picture or as a radar pattern. For application to television see Chap. 22 of this volume and references;[2] for radar applications see references[3] and Secs. 195 and 196.

IEE* (*London*), Part

The discussion of the product of gain and band width given above applies to the case of one tube in each stage. In distinction, two or more tubes per stage can be used by either (1) the method of *distributed amplification*,[1] or (2) the use of tubes in parallel with filters to divide the frequency band among the tubes of the stage. Either method permits wider bands to be amplified than is possible with a single tube in each stage. Fundamental studies by Wheeler[2] have resulted in the conclusion that for any particular type of tube there is a maximum value of the *speed of amplification*, which is defined as the quotient of the gain divided by the delay time incurred in amplifying the signal by this amount of gain. For the 6AK5 pentode this maximum value is 0.65 db per millimicrosecond.

Promising results have been obtained in studies and tests of transistor wide-band amplifiers.[3]

RADAR

195. General Properties. Specifications of a number of radars used in the Second World War are available in the literature.[4] Radars made for installation on the ground included models with carrier frequencies from 195 to 10,000 Mc, pulse durations from ¼ to 30 μsec, pulse repetition rates from 200 to 4,098 pulses per sec, receiver noise figures from 7 to 18.5 db, and band widths from 1.25 to 10 Mc.

Air-borne radars included models operating at carrier frequencies from 2,500 to 10,000 Mc with pulse durations from 0.4 to 1.13 μsec, pulse repetition rates from 400 to 2,000 pulses per sec, receiver noise figures from 11 to 21 db, and receiver band widths from 1.9 to 8 Mc.

The postwar importance of radar led the FCC to assign the following three frequency bands for general maritime radar use: 3,000 to 3,246, 5,460 to 5,650, and 9,320 to 9,500 Mc. These bands accommodate the war designs in the neighborhood of 3,000 and 9,000 Mc and, in addition, establish the new 5,460 to 5,650 band at which experience can be gained. Radars for higher frequencies have better antenna directivity but suffer greater attenuation due to rain. The choice of the best operating frequency is therefore a compromise.

The receiver of a radar is essentially a wide-band type, as discussed in Sec. 194, to which a cathode-ray display has been added. Various auxiliary circuits for the display, and often others for the receiver proper, are required to give the necessary performance.[5]

Various types of displays are available. Maritime equipments normally use the PPI (plan position indicator), a maplike presentation with the observer's location at the center. Military designs use the PPI and various other types.[6]

As typical receiver details in maritime radars,[7] the following can be mentioned:

operating frequency, approximately 9 kMc; STC (sensitivity time control) provided; over-all band width adjustable to 4 or 12 Mc, or fixed at 8 Mc; and PPI display of 10 to 16 in. diameter.

196. Receiver Design Matters. One of the methods of stating the sensitivity of radar receivers is by their *tangential sensitivity*. This is measured, as shown in Fig. 40, by determining the amplitude of pulse such that its base line is approximately tangent to the upper edge of the noise signal. Various observers have found that this corresponds to a signal-to-noise ratio of about 8 db.[1]

The over-all band width of a radar receiver can be made about equal to the reciprocal of the pulse duration for good detectability of weak signals. For accurate range determination the band width can advantageously be increased to as much as four times this value.

For holding and tracking a particular target, the radar receiver can be provided with suitable gating (to isolate the corresponding echo signal) and with a.v.c. to maintain the desired signal amplitude. In such cases satisfactory a-v-c action without low-frequency noise otherwise encountered has been obtained by providing an a-v-c filter circuit having a quick attack and a slow release time.[2]

FIG. 40. Appearance of oscilloscope in use of tangential pulse signal for measurement of the selectivity of a pulse receiver.

Radar receivers are often provided with STC (sensitivity time control), which operates automatically to reduce the sensitivity immediately after each transmitted pulse and then increase the sensitivity steadily as the more distant, and therefore weaker, echoes are received. An alternative design is a logarithmic receiver, whose output is proportional to the logarithm of the input.[3] Either STC or a logarithmic feature operates as an anticlutter means by removing the saturation from fixed objects or sea return which otherwise may obscure desired echoes at close and medium distances.

Other anticlutter methods have much in common with antijamming circuits (Sec. 183). One method is fast-acting a.v.c., often called IAGC for *instantaneous automatic gain control*, which lowers the gain promptly on the receipt of strong echoes or interference. Another method is FTC, or *fast-time-constant*, circuit, which differentiates the wave form and is useful for reducing clutter due to rainfall. Circular polarization is also beneficial in combating rainfall clutter.

Two other methods of improving radar reception have been used, especially in military service. One of these is MTI, or the *moving-target indicator*, which operates by a dual-channel feature and a delay line in the receiver so that fixed echoes are canceled. The other method of improving radar reception involves the distant object rather than the radar receiver and consists of providing at the distant point or craft a *transpondor*, which is an automatic receiver-transmitter. This offers the advantages of much stronger signals and also the means of furnishing identification information regarding the distant object.

Miniaturized i-f amplifiers suitable for radar service are described at the end of Sec. 130.

The proportioning of the second-detector circuit of the radar receiver can be facilitated by a nomogram prepared by C. W. Young.[4]

SPECIAL RECEIVERS

Numerous cases arise in which designs of radio receivers for special purposes are needed. A few such instances illustrating the wide range of requirements are given.

197. Field-strength Meters.[1] Various special features are necessary in receivers used for the measurement of field strength. Precise antenna dimensions, suitable calibrating arrangements, very stable general operation, an indicating instrument, and switching to choose the detector time constant are some of the requirements. Field-strength meters are used for the measurement of both signal strength and interfering disturbances.[2]

Field-strength meters for the v-h-f (metric) and part of the u-h-f (decimetric) bands were covered by a proposed American standard[3] issued in 1952. An instrument for the 600-Mc region was designed at the National Physical Laboratory in England, using a silicon crystal and an i-f amplifier operating at 30 Mc.[4]

198. Receivers for Radio Astronomy.[5] An outstanding aspect of the reception and study of radio waves from heavenly bodies and regions is the very low signal strength of the radiation of interest in comparison with the general noise background. As a result, the signal-to-noise ratio is far less than unity. Special methods are therefore necessary, usually consisting of rapid switching (*e.g.*, at a 500-cps rate) from the signal of interest to some suitable reference condition so that the result of many such comparisons is obtained.

Frequencies of the entire normal radio spectrum are received as cosmic radiation, as discussed in Sec. 25. One frequency is 1,420 Mc, associated with hydrogen, and 327 Mc, associated with deuterium (heavy hydrogen).

A compact astronomical radio receiver can act as a sextant for nautical use in shooting the sun in cloudy weather.[6]

199. CONELRAD Receivers. The FCC has established the CONELRAD (control of electromagnetic radiation) system as a civil defense aid in the event of an enemy airplane attack. One feature is that certain key broadcast stations receive the official notice, make an announcement, and go off the air. Many other broadcasting and other classes of stations are required to monitor one of these key stations, and upon an alert likewise to leave the air. A CONELRAD receiver[7] is one designed to perform this monitoring, and includes the following features: (1) An r-f channel tuned to the key station but not usually connected to the loud-speaker; (2) a relay whose armature is held up by the detected d.c. of the key-station signal; and (3) an alarm actuated by the release of the relay armature or by failure of the set on the fail-safe principle. In addition, the set may include another r-f channel, or a change-of-tuning feature, so as to reproduce on the loud-speaker the civil-defense instructions received on 640 or 1,240 kc, the channels assigned for this purpose.

200. Receivers with Privacy Feature.[1] For public radiotelephone service it is usual to provide some form of speech scrambling so that eavesdropping with simple types of receivers is prevented. One type of privacy equipments, described in Sec. 177, utilizes division of the voice-frequency range into several portions which are then exchanged, with or without inversion of the individual divisions. A simpler method of scrambling is to invert the entire speech band as a single unit, the usual practice being to have 1,550 cps as the center point. In this case, 1,000 cps, for example, becomes 2,100, and 2,100 becomes 1,000; similarly, 500 cps and 2,600 change places; likewise, 100 and 3,000 cps.

Warbling of the carrier frequency is also available as a privacy method. The extent of the warbling must obviously be kept within bounds in order to avoid excessive increase of the frequency spectrum.

201. Receivers Using Synchronized Added Carrier. Experimental designs have been made of receivers using added synchronized carrier at the signal detector.[2] The "Synchrodyne" receivers are of this type and include circuits for automatically maintaining synchronism of the local oscillator. For special conditions, such as when the noise exceeds the signal, the use of added synchronous carrier has been found advantageous.

Promising characteristics have been found with a system of suppressed-carrier double-side-band transmission in which the receiver recreates the carrier using only the information in the two side bands.[3] This system therefore requires no pilot carrier for its operation.

UNDERWRITERS' REQUIREMENTS

Numerous provisions for the reduction of shock and fire hazards have been established by Underwriters' Laboratories, which is sponsored by the National Board of Fire Underwriters. Receiver models examined and found to comply with these provisions are privileged to bear a label showing approval by Underwriters' Laboratories. The latest edition of the "Standard for Radio and Television Receiving Appliances" of Underwriters' Laboratories will be furnished to receiver design engineers on request to any one of their offices in New York, Chicago, or Santa Clara, Calif. This standard is a pamphlet giving the specific electrical and mechanical requirements for the approval of equipment, and covers radio receivers, television receivers, phonographs for home use, and recorders.

202. Receiver Hazards. With regard to fire hazard,[4] one of the most important requirements for a-c receivers is that the power transformer must be completely housed in noncombustible material without louvers or holes except as required for the entry of wires. The purpose of the housing is to prevent the escape of flame or molten metal in case the transformer is overloaded by the short circuit of some secondary winding.

With a-c–d-c sets, the chief fire hazard is the first electrolytic filter capacitor, which for a-c operation and a short circuit of the rectifier tube is subjected to a severe condition. The connection of the filter circuit to a tap on the rectifier-tube filament is advantageous in reducing this hazard.

Shock hazard includes exposed conducting parts such as antenna lead, ground lead, metal cabinet if used, phono tone arm if used, and shafts and setscrews of control knobs.

[4] Heaton, H. T., Preventing Fires from Electrical Causes in the Design and Manufacture of Radio and Television Receivers, *Trans. IRE*, **BTR-1** (2), 28, April, 1955.

Various requirements must be satisfied by flexible cords with regard to (1) character of wire, (2) bushing or equivalent treatment of the hole, (3) strain relief to prevent a pull on the cord being transmitted to internal connections, and (4) means to prevent the cord from being pushed into the hole.

Temperature limits for various materials inside the receiver must not be exceeded. Each wire must be suitable for the voltage, temperature, and other conditions prevailing.

A-c–d-c receivers with the chassis directly connected to one side of the power mains are permitted under certain conditions including the provision of a substantial back cover and interlock. In the case of f-m receivers for a-c–d-c operation, this has been found the most practical arrangement because it avoids the regeneration difficulties encountered with an isolated chassis.

AUTOMATIC MANUFACTURE OF RECEIVERS

203. General Types. The designer of receiver circuits, and especially of the associated mechanical features, must consider the manufacturing methods to be used. These methods include techniques adapted for automatic production,[1] especially the various forms of "printed wiring" and the modular type of construction.

The term *printed wiring*[2] is applied to any construction which produces flat wiring on a supporting board of insulation such as paper-laminated phenolic. The various methods include photographic processes, chemical etching, embossing, and other operations. The use of printed-circuit construction saves the labor otherwise needed to make the many individual connections between parts. It also affords more compact assemblies, which is often an important advantage. Further treatment of miniaturization is given in Sec. 130.

The modular type of construction for automatic manufacture[3] utilizes assemblies of ceramic wafers or disks. Each module consists of several of these disks slightly separated one above the other in a stack and provided with both mechanical support and electrical connections by means of straight bare wires going from disk to disk. Notches are provided in the edges of the disks for the wires. Each disk provides or supports one or more circuit elements, such as a capacitor or resistor, and the top disk can support a tube socket.

COLOR CODES FOR WIRING

204. EIA Code. Standard REC-108-A of EIA[4] establishes a color code for chassis wiring which includes basic functions according to body wire color and subordinate

Table 19. Body or Solid Wire Colors According to Basic Function*

Color	Function
Black	Grounds, grounded elements, and returns
Brown	Heaters or filaments, off ground
Red	Power-supply B plus
Yellow	Cathodes
Green	Control grids
Blue	Plates
White	Above- or below-ground returns, a.v.c., etc.

* From Standard REC-108-A.

classification according to tracer color. The body colors and their basic significance are given in Table 19. Other color codes will be found in other chapters of this volume.

It is also specified that, when antenna and ground connections are provided on the receiver, the antenna lead shall be blue and the ground lead black. In the case of leads for special antenna connections, combinations of blue and black are specified.

ANTENNAS FOR BROADCAST RECEPTION

A general treatment of antennas is given in Chap. 20, and loop antennas are discussed in Sec. 31 *et seq.* of the present chapter. The present section gives data on some open-type antennas and systems especially designed for broadcast reception.

205. F-m Antennas. Use of the home electric wiring as an antenna for f-m signals on the 100-Mc band has been found practical. This form of antenna, although not so good as a well-installed outside dipole, has been found an acceptable substitute and permits f-m table-model receivers to operate without the necessity of installing an outside antenna. A minor difficulty is that the results are sometimes poor at one outlet while they are good at another outlet in the same room.

In the 100-Mc f-m band extensive use has been made of folded-dipole antennas constructed of 300-ohm balanced transmission line and mounted in the top of the cabinet. Such an antenna extending across the width of a 40-in. cabinet and extending along the sides for 9 in. had an efficiency within 1 db of a good dipole used as reference standard, and had voltage standing-wave ratios of about 5 at 88 Mc, 1.5 at 98 Mc, and 3.5 at 108 Mc. A more compact design, extending across the 24-in. width of a cabinet and continuing for the full length of the 12-in. sides and then for 8 in. around the corner, thus having a total length of 64 in., had an efficiency of −2.5 db with respect to the same reference standard, and voltage standing-wave ratios of 6, 3.6, and 7, respectively, at the three frequencies already mentioned.

206. Master Antennas. Technique is available for the design of master antenna systems suitable for supplying many outlets, such as in apartment houses, and providing service on the broadcast band, the h-f international and amateur bands, and the lower television channels.[1]

Installation of antennas for furnishing 100-Mc f-m service, as well as h-f and m-f reception, have been made on a large scale in some apartment-house developments.[2] One antenna in these installations supplies one antenna coupler which delivers signal to one or two transmission lines consisting of RG-59/U flexible coaxial cable. Each of these cables supplies as many as 18 individual outlets. In this installation the outlets are directly in parallel across the transmission line; *i.e.*, no receiver couplers are used. Each run of RG-59/U is terminated at the end with a 100-ohm resistor. A polarized outlet is used in each apartment to prevent a ground being placed on the center conductor of the RG-59/U. A power outlet for the 117-volt supply of the radio receiver is provided conveniently at the same location.

208. Terminology in British References. The following glossary of British radio terms may be useful when consulting the various excellent books and journals published in Great Britain:

Accumulator = storage battery
Bush = bushing
Decoupling = use of filter to prevent feedback coupling
Earth = ground
E.H.T. = extra high tension = plate supply for cathode-ray tube
Former = coil form
Four-pole = four-terminal passive network
Gramophone = phonograph
H.T. = high tension = plate supply
Long-wave band = 900–2,000 m = 333–150 kc
L.T. = low tension = filament supply
Mains = power wires in the house for lighting and appliances
Medium-wave band = 200–550 m = 1,500–550 kc
Picofarad = pf = micromicrofarad
Radiogram = phonoradio combination
Relay = furnishing of programs over wires to homes or apartments from a master radio receiver or by wire from the studio of a radio station
Screening = shielding
Shroud = strap for holding transformer laminations
Speech coil = voice coil (of a loud-speaker)
Tag = lug
Torch = flashlight
Valve = tube
Valve holder = tube socket

CHAPTER 20

ANTENNAS

By John N. Hines[1]

The transmission and reception of electromagnetic waves used for radio communication are accomplished by radiators and collectors exposed in space and known as antennas. In this respect, an antenna acts as an efficient transformer between free space and a transmission line, or vice versa. Between the transmitting and the receiving antennas there is a combination of earth, water, air, and ionospheres which constitute the mediums in which electromagnetic waves are propagated. The action of the waves in traversing these mediums is very complex, being dependent upon many known and other unknown factors. Prominent among the known factors are the transmitting frequency, the radiation characteristics of the transmitting antenna, the orientation of the path of transmission in the earth's magnetic field, the time of day and the conditions of daylight and darkness along the path, the season of the year, the solar activity, the electrical characteristics of soil or water in the immediate vicinity of the antenna as well as along the path of the surface waves, the immediate conditions of ionization of the atmosphere at various levels, the distance between transmitter and receiver, and the characteristics of the receiving antenna.

The whole field of antenna technology has grown from the striving to launch and collect radiant energy in the most efficient ways dependent upon the empirical facts of wave propagation. If the earth were a smooth perfectly conducting sphere in a vacuum, antenna techniques, except for size, would not vary much over the entire useful range of radio frequencies. In reality, the lowest frequencies are best utilized by ground-wave transmission. These gradually blend into the frequencies where both ground waves and sky waves have separate usefulness. Gradually these blend into the frequencies for which ground waves are rendered useless and only sky waves can be usefully employed. Eventually frequencies are reached where the ionospheres no longer reflect waves and where range is limited to the diffraction region beyond the horizon. At still higher frequencies, this diffraction zone is reduced to virtual uselessness, and transmission is confined to purely optical circuits, but complicated sporadically by meteorological effects which produce mirage. Meteorology plays a greater part in wave propagation as the frequencies enter the s-h-f region. In the frequency range from beyond the point where radio waves no longer reflect from the ionosphere to the s-h-f region exists a recently discovered propagation phenomenon called *forward scatter* which greatly extends the limits of long-range communications. The different portions of the spectrum each require different basic antenna techniques, and in each portion a large variety of antenna structures has been evolved with different degrees of general or special utility.

It must be emphasized that antenna applications are dependent upon the nature of wave propagation for any frequency and transmission circuit, and for that reason the antenna engineer must also be familiar with propagation physics.

It is impossible to place on paper all the various considerations that determine the design details of an antenna. For different applications, different weights must be placed on each factor in the complex combinations of electrical, mechanical, and economical aspects of the design. Even though the same fundamental principles apply

[1] Antenna Laboratory, Ohio State University. On low- and medium-frequency antennas, the author has drawn to a considerable extent on the material on these subjects appearing in the fourth edition and prepared by E. A. Laport.

generally, a carefully engineered antenna system is an empirical entity, calling for a certain seasoned judgment gained only from experience or close study of the theory and techniques developed for various purposes throughout the years. But there is no intrinsic mystery to the subject, and the fine points merely provide those extra few decibels of superiority; and whether this superiority is worth what it sometimes costs, the designer must decide for the particular case. As in most fields, overdesign may demonstrate poor judgment as much as underdesign.

In general, it is possible to excite any antenna at any frequency simply by applying enough potential to drive a current against the impedance it presents at that frequency, whatever it may be, or to match this impedance into that of the generator so that all the power is delivered up to the point of termination. Beyond this point, the power must either be consumed in internal losses in the system or be radiated. But to radiate the power in a particular manner into space for effective utilization, the antenna must be designed to have current or aperture distributions in the radiator which shape the radiated field in a desired, as distinguished from a random, manner.

1. Definition of Terms[1]

Antenna (Aerial). A means for radiating or receiving radio waves.

Unipole or Isotropic Antenna. A hypothetical antenna radiating or receiving equally well in all directions. In electromagnetics, unipoles do not exist physically but represent convenient reference antennas for expressing the directive properties of actual antennas.

Electric Dipole (Doublet). A pair of equal and opposite charges an infinitesimal distance apart. In electromagnetics, the term "dipole" is often applied to two equal and opposite oscillating charges an infinitesimal distance apart; in this sense, it is synonymous with an electric-current element or doublet.

Antenna Array. A system of antennas coupled together for the purpose of obtaining directional effects.

Omnidirectional Antenna. An antenna producing essentially constant field strength in azimuth and a directive radiation pattern in elevation.

Unidirectional Antenna. An antenna which has a single well-defined direction of maximum radiation.

Radiating Element. A basic subdivision of an antenna array which in itself is capable of radiating or receiving r-f energy.

Parasitic Element. A radiating element, not coupled directly to the feed line of the antenna array, which materially affects the pattern of the antenna.

Dipole Antenna. A straight radiator, usually fed in the center and producing a maximum of radiation in the plane normal to the axis. A half-wave ($\lambda/2$) linear radiator is usually called a half-wave dipole. A vertical dipole antenna will radiate only theta (θ) polarization.

Loop Antenna. An antenna consisting of one or more complete turns of conductor and functioning by virtue of the circulatory current therein. A loop antenna with uniformly distributed in-phase current is sometimes referred to as a *magnetic dipole.* Such a horizontal loop antenna will radiate only phi (ϕ) polarization.

Aperture (of a Unidirectional Antenna). That portion of a plane surface near the antenna, perpendicular to the direction of maximum radiation, through which the major part of the radiation passes.

Aperture Illumination. The field distribution in amplitude and phase over the aperture.

Antenna Resistance. The power supplied to the entire antenna circuit divided by the square of the effective (rms) antenna current referred to a specified point. Antenna resistance is made up of such components as radiation resistance, ground resistance, r-f resistance of conductors in the antenna circuit, and the equivalent resistance due to corona, eddy currents, insulator leakage, and dielectric power loss.

[1] Most of these definitions are taken from (1) IRE Standards on Antennas, Modulating Systems, and Transmitters: Definitions of Terms, 1948, (2) IRE Standards on Antennas: Methods of Testing, 1948, and (3) IRE Standards on Antennas and Waveguides: Definitions of Terms, 1953.

Radiation Resistance. The power radiated by the antenna divided by the square of the effective (rms) antenna current referred to a specific point, usually where power is introduced.

Self-impedance. The ratio of the impressed voltage and the current at the feed point of a single radiating element in the absence of any influences from other radiators or ground.

Mutual Impedance. The mutual impedance Z_{21} of two coupled antennas is defined as the negative of the emf V_{12} induced in antenna 2 by the current I_1 flowing in antenna 1 divided by I_1 with the terminals of antenna 2 open-circuited. By reciprocity $Z_{12} = Z_{21}$.

Electromagnetic Wave. A wave in which there are both electric and magnetic fields. Electromagnetic waves are known as radio waves, heat rays, light, X rays, etc., depending upon the frequency.

Transverse Electromagnetic Wave (TEM). An electromagnetic wave in which both the electric and magnetic fields are transverse to the direction of propagation.

Linearly Polarized Wave. A *TEM* wave in which the electric (or magnetic) field has a constant direction at a point in space.

Direction of Polarization. In a linearly polarized electromagnetic wave, the direction of the electric-field vector. Hence, the direction of polarization is vertical in a *vertically polarized wave,* horizontal in a *horizontally polarized wave,* tangent to the meridian line of a spherical frame of reference in a theta (θ) polarized wave, and tangent to the lines of latitude of the spherical reference frame in a phi (ϕ) polarized wave. The usual frame of reference has the polar axis vertical and the origin at, or near, the antenna.

Cross Polarization. The component of the electric-field vector normal to the desired polarization component.

Fraunhofer Region. That region of the field in which the energy flow from an antenna proceeds essentially as though coming from a point source located in the vicinity of the antenna. If the antenna has a well-defined aperture D in a given aspect, the Fraunhofer region in that aspect is commonly taken to exist at distances greater than $2D^2/\lambda$ from the aperture.

Fresnel Region. The region between the antenna and the Fraunhofer region.

Principal E Plane. A plane containing the direction of maximum radiation and in which the electric-field vector everywhere lies in the plane.

Principal H Plane. A plane containing the direction of maximum radiation and in which the electric-field vector is everywhere normal to the plane while the magnetic vector lies in the plane.

Power Density (Poynting Vector). In a given direction, the time rate of energy (*i.e.,* power) flow per unit area in that direction.

Radiation Intensity. In a given direction, the power radiated from an antenna per unit solid angle in that direction.

Radiation Pattern. A graphical representation of the radiation from an antenna as a function of direction. Cross sections in which radiation patterns are frequently given are the vertical and horizontal planes, or the principal electric and magnetic planes.

Radiation Lobe. A portion of the radiation pattern bounded by one or two cones of nulls.

Cone of Nulls. A conical surface formed by directions of negligible radiation.

Major Lobe (Main Beam). The radiation lobe containing the direction of maximum radiation.

Minor Lobe (Side Lobe). Any lobe except the major lobe.

Half-power Width of a Radiation Lobe. In a plane containing the direction of maximum of the lobe, the full angle between the two directions in that plane about the maximum in which the radiation intensity is one-half the maximum value of the lobe. *The tenth-power width* is the corresponding angle between the directions in which the radiation intensity is one-tenth (-10 db) the maximum of the lobe.

Directive Gain. In a given direction and relative to an isotropic antenna, it is 4π times the radiation intensity in that direction divided by the total power radiated by the antenna. Also the radiation intensity in that direction divided by the average radiation intensity radiated by the antenna (sometimes called gain; see *power gain*).

Directivity. The value of directive gain in the direction of its maximum value.

Power Gain. In a given direction and relative to an isotropic antenna, it is 4π times the radiation intensity in that direction divided by the total power delivered to the antenna (sometimes called gain; see *directive gain*).

Radiation Efficiency. It is the ratio of the power radiated to the total power supplied to the antenna at a given frequency (power gain = radiation efficiency × directive gain).

Gain of an Antenna (old usage). The measured gain of one transmitting or receiving antenna over another is the ratio of the signal power one produces at the receiver input terminals to that produced by the other, the transmitting power level remaining fixed.

Effective Area (Effective Aperture, Absorption Cross Section). In a given direction, the power in the terminating impedance divided by the power density of the wave incident upon the antenna. For a matched antenna, it is the square of the wavelength multiplied by the power gain (or directive gain) in that direction and divided by 4π.

Effective Height (present usage). The height of the antenna center of radiation above the effective ground level. For an antenna with symmetrical current distribution the center of radiation is the center of distribution. For an asymmetrical current distribution the center of radiation is the center of the current moments when viewed from directions near the direction of maximum radiation.

Effective Height (former usage). The induced voltage at the terminals of an antenna divided by the strength of the incident electric field. In l-f applications, as applied to loaded or unloaded vertical antennas, it is the actual height of the vertical section multiplied by the ratio of the average value of rms current in that section to the rms input current.

$$h = \frac{\int_0^L I(dl)}{I_{\text{in}}} = \frac{\text{meter-amperes}}{I_{\text{in}}}$$

Band Width. The range of frequencies within which the antenna performance, in respect to some characteristic, conforms to a specific standard. Impedance band width, for example, is often taken as the frequencies at which the input impedance departs from the resistance by a certain amount in terms of power factor; or in transmission-line coupled systems, the departure of the standing-wave ratio (SWR) from unity by a specified amount.

Antenna Tuning. Resonating an antenna system to some frequency other than a natural frequency by means of reactive devices.

Antenna Loading. The procedure where lumped reactances are connected in the antenna system for the purposes of antenna tuning.

Node. Point of zero or minimum voltage or current.

Antinode. Point of maximum voltage or current.

2. Radiation Control. Almost all modern radio applications require some specified form of radiation control for power gain, antifading, reduction of interference, radio guidance, reduction of multipath distortion, or reduction of noise. Antenna technology plays an important role in the general struggle to improve utilization of the radio spectrum.

Radiation is controlled by setting up current distributions, or aperture illuminations, which produce wave-interference patterns in space having specified or desirable forms best adapted to the wave-propagation circumstances. Generally, precise control in three dimensions is necessary. The higher the frequency, the easier it becomes to achieve high degrees of radiation control, limited only by frequencies so high that structures of conductors become too small to be practical and one must resort to

horns, reflectors, and other configurations. At the l-f end of the spectrum, the limitations are due primarily to great size (and cost).

The principles of wave interference have been highly developed in electromagnetic theory, and there is a vast literature with many excellent recent contributions.[1]

At a distance of several wavelengths from an antenna only the radiation field needs to be considered. This field is characterized by the fact that the electric and magnetic components are in time phase and are perpendicular to each other and to the direction of propagation. The strength or intensity of the field is inversely proportional to the distance from the antenna.

However, close to the antenna the field structure is quite complex because of the existence of the induction field of the antenna. The intensities of these fields decrease much more rapidly than the radiation field, and for an electric dipole, for example, the two are equal at a distance equal to the wavelength divided by 2π (approximately $\frac{1}{6}\lambda$). The induction field is important when antenna elements are coupled together by virtue of their proximity. Their existence must be kept in mind when making field-strength measurements near the antenna.

3. Current Distribution in Linear Conductors. The treatment of an antenna as an open-ended uniform transmission line with uniformly distributed attenuation is not in full accord with modern physical theories. However, this viewpoint is the simplest approach to a very complicated subject and is sufficiently in accord with practical results to justify its presentation in this form in a treatise of this type.

The various conductors of a radiating system carry currents of varying amplitudes, phases, and configurations in three dimensions. The fields set up by all the infinitesimal current elements of a system, together with the reflections which occur from the earth and reflecting areas, produce a characteristic radiation pattern. The problem in design is to set up current distributions which produce a desired radiation pattern. For this purpose, two basic types of distribution may be mentioned: those derived from standing waves on the conductors, and those derived from traveling waves. The first may be coarsely said to be (for a conductor length less than $\lambda/2$) a current distribution of constant phase and variable amplitude. The second is essentially a constant-amplitude and variable-phase distribution. It aids understanding of design principles to recognize these differences, even though practical systems have both characteristics in varying proportions.

In addition to their effect on the spatial distribution of radiant energy, current distributions determine the circuit impedance of an antenna, and the engineer must have regard for this fact for a number of reasons. Many forms of radiation patterns are realizable only by designing for predetermined impedance relationships at various points in the antenna and feeder system. As antenna techniques are developed, it becomes necessary at times to depart from simple natural current distributions and set up special distributions in linear conductors, sheet conductors, and loops. Antennas are really a complex of radiating portions and feeder portions, which have to be considered together. Only in the most elementary systems can the radiators and the feeders be treated separately.

4. Stationary-(Standing-)wave Distributions.[2] On a thin uniform linear conductor of arbitrary length with its far end open, excited at one end by an a-c generator, the current distribution can be considered as the result of interference between a wave traveling outward from the generator and another wave, due to reflection from the open end, traveling backward to the generator. The resultant current distribution is

$$I(x) \doteq \frac{V_R}{2Z_0}\left[e^{(\alpha+j\beta)x} - e^{-(\alpha+j\beta)x}\right] = \frac{V_R}{2Z_0}\sinh(\alpha + j\beta)x$$

where $I(x)$ = current amplitude and phase at a distance x from the open end of a conductor of length l including the apparent elongation Δx due to end effects

[1] See references listed under General Textbooks at the end of this chapter.
[2] See reference 28.

α = attenuation constant, nepers per unit length (1 neper = 1 hyperbolic radian = 8.686 db)
β = phase constant = $2\pi/\lambda$ radians per unit length (λ = wavelength measured on the conductor)
V_R = potential at the open end
Z_0 = characteristic impedance of the conductor $\doteq$ 138 $\log_{10}$ (2 × height ÷ diameter) for a vertical grounded radiator[1]

If α is negligibly small,

$$I(x) \doteq j \frac{V_R}{2Z_0} \sin \beta x$$

The physical significance of this is as follows. A current wave enters the conductor and describes a logarithmic spiral of decrement α and negative phase rotation β (determined by the velocity of propagation) as it passes along the wire, gets inverted at the end, and returns to the generator. The phasor (vector) sum of the incident and reflected current waves at any point x is $I(x)$.

In the theoretical case of $\alpha = 0$, the amplitude of $I(x)$ will vary sinusoidally with distance and remain constant in phase except for successive reversals at points which are multiples of $\lambda/2$ from the end. In reality, radiation and heat losses give finite values to α which are normally small. This causes $I(x)$ to depart slightly from a sinusoidal distribution, especially in the vicinity of the nodes, and causes the phase to change slowly with distance except in the vicinity of the nodes where it rapidly changes its phase to substantial reversal. To a good first approximation, then, the current distribution on thin uniform linear conductors can be assumed sinusoidal for purposes of calculating radiation patterns. A comparison between theoretical sinusoidal and measured current distributions on thin wires is shown in Fig. 1. G is the electrical length of the antenna expressed in degrees.

FIG. 1. Current distribution on vertical antennas of three lengths and small cross section. Circles are measured values; solid lines, true sinusoidal distribution.

In the same manner, the potential distribution along the conductor can be written

$$E(x) \doteq \tfrac{1}{2}E_R[e^{(\alpha+j\beta)x} + e^{-(\alpha+j\beta)x}] = \tfrac{1}{2}E_R \cosh (\alpha + j\beta)x$$

If $\alpha = 0$, the potential distribution is cosinusoidal and reverses its phase at values of x which are odd multiples of $\lambda/4$, and $E(x)$ is always in quadrature with $I(x)$ at any point. For small finite values of α, $E(x)$ departs slightly from this ideal amplitude and phase distribution, especially in the nodal regions, and $E(x)$ has a phase relationship with respect to $I(x)$ which is always less than 90 deg and comes into phase with $I(x)$ every quarter wavelength from the end.

Owing to the end effect, the distance to the first potential minimum is always

[1] See reference 12, p. 288.

slightly less than $\lambda/4$ from the open end. The amount varies from 2 per cent for thin wires to 10 per cent for large-diameter conductors and for the capacitive effect of insulators.

The impedance at any point in the system, looking toward the open end, is the vector ratio $Z(x) = E(x)/I(x)$. $Z(x) = R \pm jX$ is called the impedance as seen from that point (usually of interest only at a feed point).

Experimentally determined curves of resistance and reactance of cylindrical antennas normal to a perfectly conducting ground are shown in Figs. 2a and 2b.[1] For isolated balanced antennas the values shown must be doubled. These are shown in terms of the parameter D, which is the diameter of the antenna in electrical degrees and includes the capacitance of the closed lower end of the cylinder which in all cases is 1 deg from ground. These curves have fundamental reference value.

FIG. 2a. Measured resistance of cylindrical antenna normal to perfect ground.

Empirical Distributions. By modifying the velocity of propagation and the characteristic impedance of the conductor, uniformly or nonuniformly, or by use of lumped reactances inserted in the system, new expressions for the current and potential distributions are required. Empirical distributions can be produced in this way.

5. Traveling-(Progressive-)wave Distributions. If instead of being open the end of this conductor is terminated so as to absorb all energy arriving at the end without reflecting any of it, then a traveling-wave system results. Under perfect realization of this condition $Z(x) = Z_0$ is constant for any value of x.

In the standing-wave condition, impedance variations with length vs. frequency exhibit properties analogous to resonance (at x = odd multiples of $\lambda/4$) or antiresonance (at x = even multiples of $\lambda/4$). These resonance effects are selective to frequency in varying degrees and limit the bandwidths that can be obtained. In the traveling-wave condition, selectivity is impossible unless the termination is selective.

6. Special Distributions. Arrays of conductors having predetermined current distributions, amplitudes, and relative phases of excitation produce special distributions of current in three dimensions for radiation control. By so doing, each conductor is immersed in the fields of all the others, producing energy interchanges through radiation couplings. They produce circuital effects called mutual impedances. Depending on spacing, relative current amplitudes and phases, and orientations, the mutual

[1] See reference 30.

impedance between two radiators at a given frequency is in general complex and can be vectors lying in all four quadrants. R and X can both be either positive or negative.[1]

7. Distributed Potentials Induced by Space-wave Fields. When one conductor is in the field of another, the energy exchange is by means of potentials induced in all parts of the wire. These potentials would have to be simulated by a system of distributed generators in contrast with a single generator used to excite a single radiator. Distributed generators produce a different current and potential distribution along a wire than does a single generator such as a transmitter. Therefore, mutual-impedance effects modify the shape of the current distributions from those prevailing in the absence of mutual impedance.

FIG. 2b. Measured reactance of cylindrical antenna normal to perfect ground.

In the case of receiving antennas, which are excited entirely by the field of the passing electromagnetic wave, the current and potential distributions are not like those for transmitting except for a $\lambda/4$ grounded antenna and a $\lambda/2$ antenna above ground, as shown in Fig. 3.

V-L-F AND L-F ANTENNAS (10 TO 300 KC)

With the advent of high frequencies for point-to-point communications, the low frequencies were relegated to the past in the popular mind. There has been a revival of the use of low frequencies for transmission in the auroral zones where the high frequencies are too unreliable for certain important services such as aviation. An exception to this is the recently discovered ionospheric forward-scatter mode of propagation in the v-h-f band which is unaffected by auroral disturbances. Fortunately the auroral zones are among the lowest-noise zones of the world so that, aside from the factor of propagation, the reliability and the effectiveness of low frequencies are much greater than for the high-noise zones of the lower latitudes.

The efficiency and band width of antennas whose dimensions are much less than the wavelength are essentially limited by the antenna size. Small antennas, whose maxi-

[1] See references 28, 32, 49, 56, 58, 59, 67, 68, 76, 83, 119, and 124.

mum dimensions are less than $\lambda/2\pi$, can be made to behave essentially as lumped capacitances (electric dipoles) or inductances (magnetic dipoles or loops).[1]

The power available from a small antenna can be expressed in terms of its effective area, which is $3\lambda^2/4$ sq m. However, in each instance the unavoidable loss in the coupling circuits restricts the output to only a small fraction of the power input. While the radiation pattern and hence directive gain of a small antenna remain the same as its size is decreased, the radiation resistance decreases relative to the other resistance in the coupling circuit. The resulting reduction in coupling efficiency is one of the principal limitations of small antennas. The reduction in size also imposes a fundamental limitation on band width, since a smaller antenna must be more sharply tuned to deliver its available power. Increased bandwidth can be obtained only at the expense of coupling efficiency.

V-l-f and l-f antennas are generally characterized by short electrical length with consequent low radiation resistance and high input reactance. Design techniques feature methods for maximizing radiation resistance and minimizing ground resistance, insulation loss, and reactance. Power input is limited by corona or flashover potentials. The potentials on the system are uniform within a few per cent. Useful radiation is that which is vertically polarized, and service is rendered by ground wave with some D-layer influence. Ground-system design must take into account the need to minimize current densities at collecting points and the very deep penetration of ground currents into soils of highest conductivities and even into sea water. This is the oldest branch of antenna technology, and yet there is room for additional research.

FIG. 3. Current and charge distribution in thin uniform wires for conditions of free oscillation. In the receiving case, the antenna is unloaded and oriented parallel to the electric field.

8. Fundamental Wavelength. Consider the vertical top-loaded antenna in Fig. 4. Because of its greater size at the top, there results a modified current distribution which produces a more desirable input impedance and vertical plane radiation pattern. In this figure, V = vertical length (height) of the down lead, H = horizontal length of top-loading section. D = diameter of vertical portion. Note that at any frequency

[1] See reference 99.

an antenna dimension can be expressed in wavelengths by the ratio of the physical length to the wavelength (expressed in same units as length) corresponding to the frequency, or in electrical degrees (or radians) by the product of the dimension in wavelengths and 360 deg (or 2π radians). For example, at a frequency of 10 kc, *i.e.*, 3×10^4 m wavelength, the vertical length of an antenna 300 m high can be expressed as $V = 300$ m $= 0.01\lambda = 3.6$ deg $= 0.0628$ radian.

The lowest frequency at which the antenna system in Fig. 4 is resonant is defined as the fundamental frequency, and the corresponding free-space wavelength is defined as the fundamental wavelength λ_0. The effective (or apparent) electrical length G of this antenna system at the fundamental frequency is $\lambda_0/4$, or 90 electrical degrees. For any vertical length V, the effective length is a function of the length of the top-loading section H and the diameter of the vertical section D.

FIG. 4. Empirical values for the constant K used in determining the wavelength of T antennas.

If the fundamental frequency, and hence wavelength, of this antenna system is known, its effective electrical length G at any other frequency can be obtained from

$$G = \tfrac{1}{4}(\lambda_0/\lambda) \quad \text{wavelengths}$$
$$= 90(\lambda_0/\lambda) \quad \text{degrees}$$
$$= (\pi/2)(\lambda_0/\lambda) \quad \text{radians}$$

where λ is the wavelength corresponding to the frequency.

The fundamental wavelength can be obtained from the following approximate relations or from measurements on scale models. For an antenna without top loading, or a vertical tower of uniform cross section, the following formula applies to within approximately 4 per cent.

$$\lambda_0 \doteq 1.33V \quad \text{m}$$

where V = vertical length (height), ft.

For top-loaded symmetrical T antennas the fundamental wavelength can be predicted only approximately from simple formulas, and for large-area flattop systems it usually must be estimated or measured from scale models. Many empirical factors are the cause of this uncertainty, including the ratio of horizontal to vertical lengths, the capacitance of insulators, the proximity of grounded or insulated towers, the number of conductors used and their cross-sectional configuration, reflections from the T junction, and perhaps other factors. It has been found from practical experience that the following empirical relation for the fundamental wavelength can be used for a symmetrical T antenna.

$$\lambda_0 \doteq K(V + H/2) \quad \text{m}$$

where the antenna dimensions are in feet, λ_0 in meters, and K is taken from Fig. 4. This figure was derived from 24 actual antennas which were carefully measured. The antennas were of different sizes and with several different tower arrangements. This unusual curve accounts within 5 per cent for all but four of the antennas. The corners in the curve are based on reliable data and so were not rounded out. The value at the right-hand extremity of the curve is based on three identical l-f antennas constructed in three different locations and measured by separate qualified individuals with exact concordance.

In some cases the effective electrical length G of an inverted L or T antenna can be taken as the sum of the vertical and horizontal parts in electrical degrees (or radians) provided that the horizontal distances from the junction with the vertical are electrically small. For capacitance-area loading of empirical form, calculations may be difficult. In such cases, it is desirable to use a scale model (the scale being in size

directly proportional to the wavelength) erected over a metallic plane of area very large with respect to the flattop. The supports should also be modeled and the location of antenna and guy insulators simulated. For reactance measurements, the cross section of the antenna conductors should also be to scale.

9. Radiation Resistance and Field Strength. The radiation resistance can be increased by increasing the vertical length (see Fig. 5) and/or by producing, as nearly

Fig. 5. (*Left*) Radiation resistance for electrically short antennas vs. height of vertical portion (degrees) and (*right*) ratio of currents at top and base of vertical portion.

as possible, a uniform current distribution on the vertical portion of the antenna. The latter is usually done by some capacitance loading at the upper end in the form of an inverted L, a T, or a large flattop in the form of a ring or spider.

The radiation resistance of a loaded antenna can be calculated from the following (see Fig. 5).

$$R_r = \frac{30}{\sin^2 (L + B)} \left[\frac{4L^2}{3} \sin^2 B + \frac{2L^3}{3} \sin 2B + \left(\frac{17}{30} \cos 2B - \frac{7}{30} \right) L^4 \right] \quad \text{ohms}$$

where L = vertical length (height), deg

B = effective lengthening of the antenna due to the top loading, deg; $L + B = G$

When $B = 0$, $R_r = 10L^2$ (L in radians). The above relationships are valid for $L \leqq \lambda/12$ ($L \leqq 30$ deg) and are shown in Fig. 5.

If one assumes a linear current distribution on the antenna, as shown in Fig. 5, then

$$I_{top}/I_{base} = B/B + L = 1 - L/G$$

where L, B, and G are expressed in degrees.

It is a great convenience to determine l-f antenna performance in terms of meter-amperes in the vertical portion (see definition of effective height). In most l-f antennas, the current distribution on the downlead is linear, and the ratio of current near the flattop to that near the base can be accurately calculated from the electrical dimensions, as indicated above, permitting in turn an accurate calculation of the meter-amperes provided the current can be observed at the lower end of the downlead,
FIG. 6. Meter-amperes required to produce given field at a given wavelength.

above all tuning apparatus. Field intensity is directly proportional to meter-amperes at any one frequency. Since a perfectly efficient λ/12 vertical antenna with 1,000 watts radiated power gives a field of 187 mv per m at 1 mile, an excellent reference for determining radiated power is available. (This reference is used because longer vertical antennas begin to provide some gain by vertical directivity.) Then if the total antenna resistance can be measured and the total power input determined, the radiation efficiency can be computed from field strengths (see Fig. 6).

The maximum field intensity possible with a given power input is the objective of all antenna designing. With l-f systems the cost per decibel of improvement at times may be very great, especially at the lowest frequencies.

The measurement of antenna resistance of antennas of very short electrical length is a difficult operation and requires special power oscillators to permit the use of thermocouple

ammeters having internal resistances small with respect to that of the circuit being measured. The resistance-variation method is also difficult unless special heavy-duty standard-value resistors are provided. The reactance-variation method is difficult because of the range of variability required in a heavy-duty tuning device. The r-f impedance bridge is an excellent instrument for such measurements.

The most convenient method of measuring antenna performance is by field-intensity measurements at a standard distance. Since large antennas which are multiple-tuned are not point-source radiators, substantial distances are required for observing performance of the v-l-f systems. For antennas with single tuning, distances as close as one wavelength may be used for measuring the radiation field. For wavelengths shorter than 1,600 m, 1 mile is a desirable standard distance, measured from the downlead.

10. Scale-model Measurements.[1] Valuable data on an l-f antenna can be obtained quickly and economically by h-f scale-model measurements. Two very important values, reactance and fundamental wavelength, can be determined accurately using laboratory instruments such as a Q meter or an r-f impedance-measuring device.

Resistances of ground, conductors, and insulators cannot be simulated. It is, therefore, desirable to build the scale model over a large continuous metallic plate acting as a perfect ground. The linear and cross-sectional dimensions are to the same scale. Towers and guys can be simulated precisely, and the effects of placement of insulators in supports and guys can be measured.

The fundamental wavelength can be measured by connecting the downlead to the ground plate and shunt-exciting the system with very loose coupling from a buzzer. The latter must be shielded. The emitted wavelength is measured by reception using a calibrated receiver. Also any of the familiar techniques of measurement of resonance in the antenna with a coupled oscillator may be used if preferred. The buzzer method is very simple and satisfactory.

Reactance can usually be measured over the range of values of interest using a Q meter. For conditions of high Q values, body effects near the antenna produce errors which can be eliminated by manipulating the Q meter from a distance. Since capacitive reactances are being measured, appropriate methods must be employed.

Scales as extreme as $\frac{1}{100}$ of natural size have proved successful with careful measuring techniques. Scales of the order of $\frac{1}{25}$ are more easily measured, but the model may be very large. The ease with which a number of empirical constructional details can be measured and compared permits the final design to be quite thoroughly evolved in the model stage. The potentials, insulator arrangement, conductor arrangements, rigging details, support locations, tower heights, etc., can be developed as far as desired.

The principle of similitude upon which model tests are based can also apply in the opposite direction by using, for instance, v-h-f models for microwave antennas, where the enlarged antenna may be more easily measured and developed than at natural size. In all scale-model work, the frequency used is proportional to the scale of the model. At $\frac{1}{50}$ scale, 50 kc is simulated by 2.5 Mc.

11. Reactance. The reactance of the antenna at the operating wavelength λ is an important value to determine so as to know the required size of the antenna load coil (l-f antennas always have a negative reactance) and the antenna potentials encountered. The reactance must be minimized to reduce loading inductance (and load-coil resistance) and to reduce insulation loss even when potentials are far below that which produces corona. This also reduces the selectivity of the antenna system, permitting higher keying speeds without excessive telegraph distortion, or greater frequency range for telephony. Reactance is reduced by increasing the top-loading capacitance, increasing the cross section of the antenna with cage or flat multiple conductors, or both. As a first approximation, the antenna can be considered as a lossless transmission line, since the reactive component of the input impedance is usually very much greater than the antenna resistance. In this case, the input reactance is

$$X \doteq -jZ_0 \cot G \qquad \text{ohms}$$

[1] See reference 28.

where G = effective electrical length of antenna, deg

$$Z_0 = \sqrt{L/C} \doteq 138 \log_{10} \frac{2 \text{ length}}{\text{diam}}$$

L = inductance per unit length
C = capacitance per unit length

These relations are satisfactory for $G \leqq 30$ deg.

It is seen that cot G is important but is determined by the electrical size of the antenna and has a large influence on its cost. For a given length and size of structure, cot G is constant. Further reduction of reactance must therefore be made by reduction of Z_0, which is done by decreasing inductance and increasing capacitance per unit length. There are mechanical limitations to cages or other forms of multiwire conductors because of wind and sleet, the increased sags and tower loadings, and the
FIG. 7. Increase in capacitance of cage vs. single wire.

multiplied problems of vibrational stress and fatigue. Figure 7 shows the increase in capacitance per unit length that was obtained for a top-loading cage in terms of percentage increase over a single wire and illustrates in general how the capacitance per unit length of a vertical l-f antenna can be increased by increasing the cross section. Of course, there is a point where mechanical objections outweigh electrical advantages.

12. Antenna Potential. The potential V_a at the feed point of a vertical l-f antenna (near ground) for a power input W into the antenna impedance $Z_a = R_a - jX_a$ is

$$V_a = I_a Z_a$$

The antenna current $I_a = \sqrt{W/R_a}$.

Most l-f antennas (or any electrically short antenna) have a reactance large with respect to the resistance, so that usually

$$|V_a| \doteq I_a X_a$$

The antenna potential is kept to a minimum for practical reasons of simplifying the insulation and avoiding corona or flashover. Therefore, the reactance of the antenna is made as low as practicable for a given total antenna resistance and power input.

There is a rise in potential along the antenna above the feed point, the amount varying with the electrical length of the system and depending upon the configuration

of the conductors. For a uniform vertical antenna, the maximum potential becomes

$$V_{max} \doteq \frac{V_a}{\cos G}$$

In the case of an antenna with a very-high-capacitance flattop,

$$V_{max} \doteq \frac{V_a}{\cos L}$$

where L = vertical length (height) of antenna, deg.

Prevention of corona, pluming, and flashover is a matter of both conductor and insulator design. Potential gradients must be kept below critical values for the ionization of air at the altitude of the site, under all meteorological conditions. Moisture films on insulators and drip water on conductors often increase losses or cause corona or plume formation, especially in still air. Adequate allowance has to be made for insulation in any case, but when antenna potentials surpass 100 kv, very special design problems are involved even at sea level; if altitudes of 5,000 to 10,000 ft are encountered at the site, the power may be severely limited, or the fundamental design of the system affected. In the latter case, it is simpler to employ self-supporting towers as radiators to attain low gradients for relatively high potentials by virtue of the large cross section of the tower. This centers the flashover problem in the base insulation, where it is not too difficult to take the required precautions for satisfactory design.

13. Antenna Resistance. The electrical design of an l-f antenna must maximize radiation resistance and minimize conductor, insulation, and ground components of resistance. In the antenna circuit is also the tuning inductance, the resistance of which must also be minimized. In a well-designed system, ground and tuning-coil resistances are the principal sources of serious power loss, and special attention must be directed to these matters to obtain maximum radiation efficiency.

14. Multiple Tuning.[1] V-l-f antennas often have radiation resistances which are only a fraction of an ohm. To obtain a radiation efficiency even as high as 6 per cent it has been necessary to use several downleads from the horizontal section and tune each downlead separately. The antenna is fed from one point only. This technique of multiple tuning was an outstanding development in the improvement of v-l-f antenna efficiency. The use of a separate ground system under each downlead reduces ground-current densities and, therefore, total ground resistance, because the total antenna current is divided among the several ground systems. The radiation resistance as seen from one downlead increases as n^2, where n is the number of multiple-tuning downleads.

15. Ground Systems. The reduction of ground resistance starts with the selection of the site, which should be an area of highest available conductivity to a considerable depth and for a distance of more than $\lambda/2$ from the antenna. The site need not be topographically flat although an undulating surface complicates construction. Surrounding hills or mountains should have an altitude which is a small part of a wavelength to avoid shadows and high attenuation for ground-wave propagation. From the standpoint of ground-system resistance alone, however, conditions beyond $\lambda/2$ from the antenna are relatively unimportant.

The depth of the soil of good conductivity is important because of the very deep penetration of earth currents at low frequencies. In general, however, the earth is a relatively poor conductor and provision must be made for returning these currents to the feed point at the base of the antenna. A large radial ground system buried in the ground surface will collect currents due to the field in space over it and will guide them back to the feed point. It is often economically impractical to use ground systems of the radial type longer than about 500 m, and this may be but a small portion of a wavelength. The fields beyond the wires set up ground currents which return to the feed point through the soil. Therefore, in this case a considerable portion of the

[1] See references 103, 104, and 110.

ground current returns to the feed point at the antenna base under the ground system, tending to produce high current densities at that point. If long ground rods are attached to the ends of the wires, these will intercept some of the ground currents near the surface where they have the greatest magnitude and refract some of the current into the wires from underneath, but the deeper currents will still pass under the system and the greater portion will be concentrated in the soil as they approach the feed point. Therefore, special means must be taken to collect these currents returning from a great depth in a manner to minimize current densities in the soil and thus reduce ground-system resistance.[1] A circle of long ground rods attached to the ground wires a short
FIG. 8. Penetration of ground current. Skin thickness $S = (4\pi^2 \alpha_{emu} f_{kc} \times 10^3)^{-1/2}$ cm.

distance from the feed point is desirable, as is also a large pipe driven deep into the soil directly under it and connected into the ground system. The length and number of radial wires are quite empirical, depending upon frequency, soil characteristics, and economics.

Another method of ground-system design for v-l-f systems is to employ from one to several circles of four to six short star ground meshes, each of six to twelve 100-ft radial wires with long ground rods at their ends. From the center of each star a conductor is brought back above ground, or insulated from ground, to the feed point or multiple-tuning point. When more than one circle of such stars is used, ground-equalizer inductors are inserted in the shorter return wires so as to equalize the currents collected from each star. This technique reduces current densities in the soil by collecting ground currents in equal amounts from a large symmetrical area surrounding the antenna downlead.

Figure 8 shows depths of penetration of earth currents for various soil conductivities and frequencies. Approximately 90 per cent of the power loss in the soil occurs within

[1] See reference 121.

the so-called skin thickness, which is that depth at which the current density has diminished to 37 per cent of that at the surface.

Capacitance grounds, or counterpoises, have certain merits which have long been recognized.[1] Instead of collecting ground currents by conduction from the soil, a large capacitance area composed of a system of wires a few feet above the earth is used. A virtually uniform electric-field distribution exists under the counterpoise and causes an equally uniform distribution of earth currents beneath. The fringe effect increases its effective area a few per cent. The area covered by a counterpoise should be as large as practicable to minimize ground losses. A small counterpoise located near the base of the downlead or tower, sometimes called a ground screen, may in some cases reduce local ground losses when used in conjunction with a buried-wire system.
FIG. 9. (a) Heavy-duty strain insulator, safety-core type, preloaded, oil-filled. (b) Safety-core strain insulator, preloaded link-core type.

16. Antennas for L-f Broadcasting. In those countries using the frequencies from 160 to 265 kc for broadcasting, there has been economic justification in employing antennas operating at or near the fundamental wavelength ($G = 90$ deg). This results in a relatively high radiation resistance and low reactance. In Europe there has been rather general adoption of a T-type single-wire antenna supported between two very high towers (as high as 250 m in some cases).

Droitwich Antenna.[2] A typical example which has been thoroughly described in the literature is that of the BBC station at Droitwich, England. A T antenna with a flattop 550 ft long and a downlead of 630 ft is supported between two towers 700 ft high and spaced 800 ft. The antenna consists of one wire. At the operating frequency of 200 kc, the impedance is $21 + j0$; at 190 kc, it is $17.5 - j41$; at 210 kc, it is $24 + j41$ ohms.

Sometimes, to correct for antenna selectivity, antenna-coupling networks are applied which equalize the antenna impedance over a range of 4 to 6 kc each side of the carrier frequency. High single vertical radiators of large cross section, derived from the tower itself or by employing supported vertical wires around the tower to effect a large cross section, have the characteristics of lower intrinsic selectivity and high radiation efficiency.

17. High-tension Insulation for Wire Antennas. Very serious electromechanical problems are encountered in the insulation of large l-f antenna systems which must

[1] See reference 108.
[2] See reference 105.

operate at high power inputs. Long spans, large conductors, heavy downleads, large total projected areas exposed to wind and sleet, and minimized sags so as to keep effective heights at a maximum all contribute to enormous stresses at the insulator locations. Maximum electrical duty occurs simultaneously with maximum mechanical duty. Insulators must be of lowest possible capacitance, and the number used in parallel must be a minimum. Typical insulators with high mechanical strength for use with very-high-tension antennas are shown in Fig. 9.

18. L-f Radio Range Antennas (200 to 400 Kc). The use of low frequencies for radio guidance in aviation on a large scale in the form of four-course radio ranges, the German Zonne system, and radiophares generally has led to the vertical tower radiator for the elimination of night effect. Any emission of horizontally polarized energy from such systems causes large errors at night in courses and in direction finding. The Adcock type of radio range is now standard in the United States and Canada, uses four radiators (square array) or five (quincunx array) approximately 125 ft high spaced about 600 ft on a diagonal. These are usually base-insulated self-supporting towers.

Fig. 10*a*. Measured resistance of various whip antennas mounted on an 8-cwt truck with truck chassis as ground: (1) 8-ft single rod; (2) 12-ft single rod; (3) 16-ft single rod; (4) 8-ft V aerial, 60 deg on common base insulator; (5) 12-ft V aerial, 60 deg on common base insulator; (6) 16-ft V aerial, 60 deg on common base insulator.

There are several evolutionary versions of radiators and ground systems for the four-course ranges. With a ground system of fifteen 100-ft radial wires (buried) with end ground rods, for each radiator, the radiation efficiency is generally of the order of 8 to 10 per cent. Ground screens in the form of elevated metallic counterpoises about 30 ft square under the tower-base insulators are also used. They are series-tuned, and two outer radiators on a diagonal operate together to produce a figure-of-8 field-intensity pattern keyed systematically with the Morse A interlocked with N keying on the opposite diagonal pair. As power is switched between the two pairs of diagonal radiators, signals in the overlap region where the field intensities are equal produce a constant uninterrupted tone which provides a fixed track for guidance of aircraft. The ability of the ear to distinguish volume levels from the two alternated patterns gives a course width of about 3 deg. Just at the place where the A or N keying becomes observable each side of the course is a narrow angle called the *twilight zone*, and aircraft ordinarily fly in the right-hand twilight zone. Between courses the A or N signals predominate.

When equal power is fed to the two halves of this system, reciprocal 90-deg courses are set up. If the power is lower in one pair, its radiation pattern is smaller than the other and reciprocal courses result but the courses are said to be *squeezed.* When both power and phase differences in the radiator currents are other than 180 deg in each pair, nonreciprocal courses are obtained. This is called *course bending.* These combinations are used to set range courses at angles best suited to airway routings in the four directions. The antenna system is energized through a goniometer, the rotation of which will turn the entire radiation pattern to the orientation desired.

The four-tower nonsimultaneous range switches the four towers into parallel in-phase feed when voice broadcasting is required, and during this interval the range courses are eliminated. The simultaneous range using five towers permits the four outer ones to transmit range courses continuously for guidance while the center tower radiates voice signals when required.

19. Whip Antennas. Whip antennas used on vehicles for transmission of h-f waves present much the same basic design problem as the electrically short l-f antenna. Radiation efficiency is intrinsically low, and care must be taken that it is no lower than necessary. In such systems tuning-coil loss and ground loss consume almost all of the transmitter power, and radiation efficiencies of the order of 0.5 to 2 per cent are common in the 2- to 8-Mc band. Base-insulator leakage and capacitance should be as low as practicable. Anything that conditions of service permit which will decrease the antenna reactance will contribute much to over-all improvement in efficiency. Some typical whip-antenna data are shown in Fig. 10*a* and *b*.

FIG. 10*b*. Measured reactance of whip antennas: (1) 8-ft single rod; (2) 12-ft single rod; (3) 16-ft single rod; (4) 12-ft V aerial, 60 deg on common base insulator; (5) 16-ft V aerial, 60 deg on common base insulator.

20. Beverage (Wave) Antenna.[1] This type of antenna, one of the most effective l-f directive receiving systems to be used commercially, is a long transmission line. It is named after its inventor, H. H. Beverage, but is also called the *wave antenna.* In its very simplest form, the Beverage antenna is a single straight horizontal wire a few feet above grade level, the length being anywhere from one to several wavelengths.

[1] See references 106 and 107.

FIG. 11. Houlton antenna system for receiving transatlantic long-wave signals.

The characteristic impedance of this wire unbalanced to ground is roughly calculable by using the image in the ground as the second conductor in a parallel-wire system. The receiver is coupled in at one end of the line, and the other end is terminated in a resistance equal to the characteristic impedance. Stable ground systems are necessary at both ends.

The long open-wire transmission line pointed in the direction of a passing wave has a high degree of exposure to the horizontal component of the wave front because of the wave tilt that earth losses produce in vertically polarized low-frequency waves traveling along the surface of the earth. This induces in the line a continuous series of emfs that are propagated along the wires in the form of a traveling wave. That is, a passing wave sets up a traveling wave in the wire which starts at the distant end (in the direction of arrival of the passing wave) and is propagated toward the end where the receiver is situated. In this manner the entire wire receives energy from the passing wave so the effects are cumulative at the receiver. Energy collected from a passing wave traveling in the opposite direction is completely dissipated in the terminating resistor and so does not enter the receiver. Waves arriving from the sides have relatively little effect on the receiver. Hence, this antenna has high directivity in the horizontal plane.

This antenna is suitable only for reception since ground losses are relatively high compared with the radiated energy in transmitting.

The Beverage antenna has many useful forms which are specially adapted to long-wave reception, to short-wave reception, to bidirectional and unidirectional selectivity, for vertical and horizontal polarization, etc. A thorough treatment of these is impossible here, and detailed data must be obtained from the original and subsequent papers on the subject.

Directivity may be sharpened by using two or more antennas in an array. This has been done in the Houlton system, shown in Fig. 11, which is used for transatlantic telephone reception on long waves. One of the several forms of antenna used in this application is that which couples the receiver to the end of the antenna that is nearest the transmitting station.

A two-wire line is used to achieve this in the following manner. Waves arriving from the preferred direction act upon the two wires in parallel to ground, and the induced wave of energy in the wire travels to the distant end where it encounters a reactive network called a reflection transformer. This device reverses the phase of the wave in one of the wires and reflects the energy from the end back to the receiver, the reflected wave of energy now traveling in the two wires balanced to ground.[1] The receiver coupling network terminates the line and absorbs all the wave energy in actuating the receiver. A wave entering the system from the reverse direction travels along the two wires in parallel against ground, produces no potential difference across the balanced termination, and therefore has no influence on the receiver. Instead, the circuit to ground is terminated in the characteristic impedance of the parallel-grounded system, and the unwanted wave is completely dissipated in a resistor.

MEDIUM-FREQUENCY ANTENNAS (300 TO 3,000 KC)

At the lower frequencies, below 3 Mc, where ground-wave absorption is not too excessive, or at frequencies below about 5 Mc, where a low angle of radiation is required, the grounded vertical antenna is extensively used with vertical heights that range from only a few tenths of a wavelength to over one-half wavelength. This type of antenna is resonant when its effective length (height) is one-quarter wavelength. In general, the radiation is vertically polarized in an omnidirectional pattern in the horizontal plane.

The radiation-pattern characteristics of the grounded vertical antenna should be such as to confine its radiation to angles sufficiently close to the horizon that the nearest point to the transmitter at which the sky wave returns to earth is just beyond the limits of the ground wave to prevent severe fading. A vertical $\lambda/2$ structure (unloaded) is ideal but sometimes impractical because of its height.

[1] A similar effect is obtained by grounding one wire and leaving the other open-circuited.

The efficiency of these antennas depends upon the ratio of the radiation resistance to the total resistance of the antenna system, which includes loss resistance in the antenna, coupling system, and ground system; the latter losses are quite serious for antennas shorter than $\lambda/4$. From an efficiency point of view, the vertical $\lambda/2$ antenna is the optimum because the radiation resistance is very much greater than the loss resistances.

The shorter vertical antennas are generally brought into resonance by top (capacitive) loading or base (inductive) loading. Top loading is highly desirable, as in l-f application, because this increases the radiation resistance.

The prime interest in the m-f band has been, and still is, in the standard broadcast band (535 to 1,605 kc) because of its commercial aspects. Each station is assigned a carrier frequency, a 10-kc channel (the frequency band occupied by the carrier and two side-band frequencies with carrier in center), beginning at 540 kc.

When broadcasting began, the antennas used were smaller versions of the types previously used for lower frequencies. When the possibilities for getting higher field strengths along the ground by using high vertical radiators became known,[1] and greater knowledge of wave propagation in this band was obtained, a period of antenna development began which led to definite optimum designs,[2] which are physically and economically realizable. While studies of antenna structures were being made, other detailed study was directed to ground systems, and again some definite practical optimum designs resulted.[3] This work placed broadcast-antenna engineering on a firm foundation, which, together with the vast information on wave propagation by ground-wave and ionosphere reflections, has permitted an intense utilization of this band of frequencies for broadcasting services. This paved the way for the use of directive antenna systems which further increased the utilization of the limited number of channels for an ever larger number of stations and increased power.

Because of a number of fortunate natural circumstances, broadcast-antenna engineering is far simpler than that for most other frequency bands. For instance, a substantially perfect ground can be built under the antenna, permitting high radiation efficiency. Within realizable heights of structures, the vertical radiation pattern can be adjusted for maximizing the ground wave and minimizing the sky wave, thereby decreasing the annular zone of overlap of the two and giving a high degree of effectiveness to both types of propagation by concentration of radiated power at angles close to the horizon. With modern data, broadcast-antenna performance can be predicted and measured with a remarkable degree of precision.

21. Nondirective Broadcast Antennas. Vertical polarization is required for broadcasting in this band, and vertical radiators are required to produce it. One steel tower used as a radiator costs less than two towers supporting an equivalent wire antenna and eliminates field distortion caused by currents induced into the supporting towers. Hence present-day broadcast antennas are almost exclusively the tower-radiator type, either guyed or self-supporting. Structures having uniform or nearly uniform cross section are necessary to assure a predictable vertical radiation pattern from a predictable current distribution. Top loading, sectionalizing, and combinations of these two techniques are occasionally employed to produce an optimum vertical directivity with limited tower heights. Tower radiators have further advantages derived from their relatively large cross section, which provides a lower characteristic impedance than a wire antenna, with lower potential gradients for the same power, lower reactance, and greater band-width capability for a given impedance variation.

22. Current Distributions and Vertical Radiation Patterns. As the electrical length of a uniform vertical conductor is increased, a larger and larger portion of a complete near-sine wave of current is distributed on it. In space, each element of length produces a field whose intensity is directly proportional to its current amplitude. The integrated fields from all parts of the antenna, together with those reflected from the ground, interfere in varying degrees from complete addition to complete cancella-

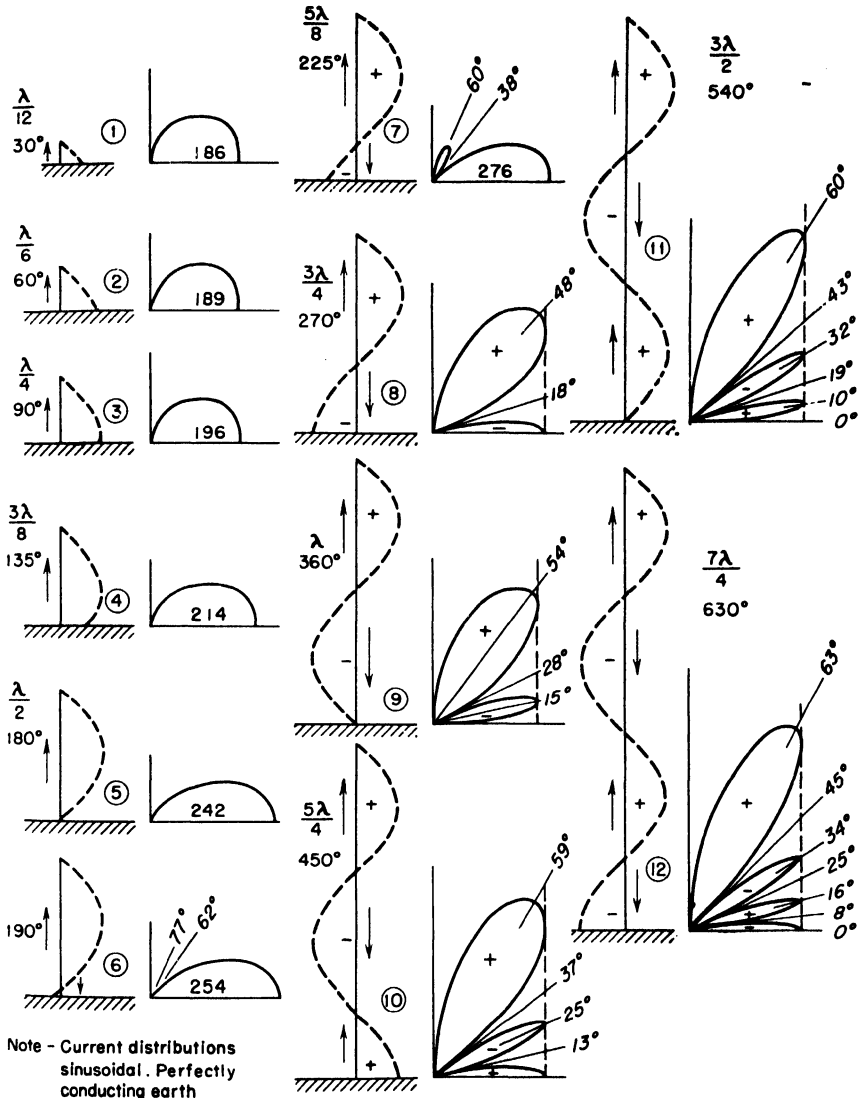

Fig. 12. Vertical field-intensity patterns for vertical antennas. The number shown in the patterns is the effective field in the horizontal plane at 1 mile for 1 kw radiated.

tion, for different vertical angles. The over-all result of this interference in the half space above ground is called the *vertical radiation pattern.* For typical broadcast applications it is given in terms of relative or actual field intensities. Antenna lengths which slightly exceed $\lambda/2$ of sinusoidally distributed current produce a vertical radiation pattern flattened toward the horizon, and this vertical directivity causes a gain in field intensity along the ground. Starting from very short length, the pattern of which is a semicircle through any vertical plane through the axis of the antenna, the

vertical pattern changes very slowly with height until it exceeds $\lambda/4$. Between $\lambda/4$ and $\lambda/2$, the pattern flattens considerably. Greatest field intensity along the ground occurs with a height of $5\lambda/8$ accompanied by a secondary high-angle lobe which is undesirable for its effect on short-distance sky-wave interference with the ground wave at night.[1] Beyond $5\lambda/8$, the ground lobe rapidly contracts, and energy is transferred to the high-angle lobe and thus becomes unsuitable for broadcasting.[2] Thus, from the standpoint of horizontal gain, $5\lambda/8$ represents a maximum condition for natural current distributions. If special means are taken to prevent a reversal of currents below the upper half wavelength of the radiator, further horizontal gain can be
FIG. 13. Polar patterns of the field-strength distribution for vertical antenna over perfect earth when the currents in successive dipole sections are cophased.

obtained with increasing antenna height. This scheme, due to Franklin, is exemplified in Fig. 13.

The dependence of the vertical radiation patterns on current distribution and antenna height is shown in Figs. 12 and 13. In Fig. 12 diagrams 1 and 2 conform to the polar equation

$$f(\theta) = m \sin \theta$$

where m = proportionality constant = effective field at 1 mile for 1 kw radiated
θ = polar angle measured from the axis of the antenna

Diagram 3 has the equation

$$f(\theta) = \frac{m \cos (90^\circ \cos \theta)}{\sin \theta}$$

All diagrams conform to the more general equation derived from a sinusoidal current distribution in a vertical antenna whose lower end is at ground level, and for total electrical length G deg,

$$f(\theta) = \frac{m \cos (G \cos \theta) - \cos G}{\sin \theta (1 - \cos G)}$$

The angles shown in Fig. 12 are the complements of the angle θ.

[1] See reference 20.
[2] See references 70 and 118.

Values of the coefficient m in millivolts per meter over perfectly conducting earth at 1 mile with 1,000 watts radiated are shown in the various diagrams. It is important to note that for diagrams 1 to 3 (a range of heights most frequently encountered in practice) the value of m increases only 5 per cent in going from very small height to a full $\lambda/4$; in going to $3\lambda/8$ it increases only 15 per cent over that for a very short radiator.[1] These facts have an important bearing on antenna economics but are contingent upon simulating virtually perfectly conducting ground by using a suitable ground system.

The FCC requires that all applicants for new, additional, or different broadcast facilities shall specify a radiating system (antenna and ground system), the efficiency of which complies with the requirements of good engineering practice for the class and power of the station. That is, the licensee must request authority to install a new antenna system or to make changes in the existing system which will meet the minimum-height requirements or submit evidence that the present antenna system meets the minimum requirements with respect to field intensities (these requirements are listed in reference 136).

FIG. 14. Notations used in developing the vertical radiation characteristics.

The primary service area of a broadcast station is important from a service and commercial point of view. The ideal antenna for high-powered broadcast stations that provide both ground-wave and sky-wave service should have a vertical radiation pattern such that the sky-wave signal does not interfere with the desirable ground-wave service. The nighttime primary service area would then be practically as large as the daytime area since the fading or distortion wall would not be the limiting factor. It is further desirable that the sky-wave signal strength rise rapidly in order to limit the intense fading area to a narrow band. An antenna that radiates practically no energy at angles above 50 deg from the horizon is shown in Fig. 14.[2] This angle can be varied from 40 to 60 deg with only a small increase in high-angle radiation by changing the current ratio $m = I_B/I_A$. At high angles, the radiation from the upper section, assumed to be 0.5λ long, is 180 deg out of phase with the radiation at these angles from the lower section. By proper choice of excitation currents the fields can be made nearly equal and will cancel.

The optimum antenna dimensions for minimum radiation above 50 deg using a 0.5λ upper-element length are a lower-element length of 0.334λ (120 electrical degrees) and a center height of the upper element of 0.584λ (210 electrical degrees). For these dimensions the value of the current ratio for a null at $\theta = 50$ deg is $m = 0.69$. The effect of the current ratio on the normalized vertical pattern $f(\theta)$ for this antenna is shown in Fig. 15. The theoretical gain of this antenna is about 14.5 per cent compared with a 0.53λ (190 electrical degrees) antenna, or about 41.5 per cent referred to a $\lambda/4$ antenna. The characteristics of the antenna have been verified using antenna models.

The performance of this antenna is compared with that of a 0.53λ antenna in Fig. 16. The sky-wave signal values are for 50 per cent of the time. The center of the fading zone is moved from 127 to 164 miles. The width of the 2:1 sky-wave to ground-wave signal ratio has been reduced from 36 to 24 miles.

[2] See reference 144.
FIG. 15. Vertical-radiation characteristics for various current ratios m, when A is 120 deg, B is 180 deg, and H is 210 deg.

23. Obstruction Lighting. When an antenna system is designed, the regulations regarding the lighting of high structures that constitute obstruction to aviation should be carefully investigated and the necessary details anticipated in the design. Regulations for lighting and painting vary in different countries and with remoteness from airports and established airways. Lighting circuits often must include flashing beacons and spare lights with automatic transfer in case of failure. In some types of antennas the design is seriously affected by the needs of obstruction lighting. Since the antenna system must function correctly with the lighting circuits, all operating measurements must be made accordingly.

When towers are used as radiators, lighting power must either pass through all the coupling and tuning devices or by-pass them through double-conductor chokes of very high r-f impedance or through special toroidal transformers with air spacing between windings, such as the Austin tower lighting transformers.
FIG. 16. Comparison of the fading range of a 0.53λ antenna and the proposed antenna. Both antennas produce a field of 1,770 mv per m at 1 mile at 1,000 kc over earth with a conductivity of 10^{-13} emu.

The latter has the characteristic of low capacitance and very high flashover potential between windings. Several versions are available, including one built into a safety core base insulator and immersed in transil oil and capable of withstanding extremely high r-f potentials.

24. Bonding between Sections of Tower Radiators. Special care is required during construction to ensure good electrical contact between tower sections. Good electrical bonding may be required across the joints between vertical sections. To aid in providing good electrical conductivity throughout the length of a tower, galvanizing of the steel is desirable. Towers used as supports do not require galvanizing except in situations where painting is not required for aviation obstruction marking, in which case the spelter provides the necessary protection against corrosion. Where painting is required, the paint will serve as adequate protection when renewed at intervals specified to keep the colors bright. For a tower radiator the paint goes on over the galvanizing.

25. Ground Systems.[1] Efficient antenna systems for operation at these frequencies are usually designed to work with a radial-wire ground system buried just below the ground surface to provide a low-loss return path for antenna base currents. A ground system consisting of 120 buried radial wires (depth of burial sufficient for protection only) $\lambda/2$ long provides a virtually perfect grounding terminal. This length is sufficient to collect earth currents due to the antenna field above ground over the top of the ground wires, and only a negligibly small amount of earth current is collected from beyond the ground wires. Such a system provides a radiation efficiency in typical cases of 95 to 98 per cent in terms of short-distance field intensities realized. A further advantage of this system is with antifading antennas, where the high-angle radiation pattern retains its theoretical form due to the very small reflection losses to waves reflected from the area of the ground system, which functions as a perfectly reflecting surface.

To obtain the maximum efficiency of which an antenna is capable, a good ground system (or counterpoise) must be employed. The FCC sets forth that, at the present development of the art, the ground system for a grounded vertical antenna in the standard broadcast band should consist of buried radial wires at least $\lambda/4$ long. There should be as many radials evenly spaced as practical and in no event less than 90 (120 radials of 0.35 to 0.4λ long equally spaced is considered an excellent ground system, and in case of high base voltage, a suitable base screen should be employed).

In radial ground systems as large as these, the electric flux from the antenna terminates on the ground wires from above, and the current densities under the wires are very low. For shorter wires, where earth currents return to the system from beyond the wires, ground rods at the ends may be justifiable, as with l-f systems. There is no need for circumferential bonding of the radials.

Directive antennas employing two or more radiators require a separate radial ground system for each up to the points where the wires of one system cross those of another, at which points they can be bonded and the projections eliminated.

The antenna input impedance is influenced by the number and length of the radial ground conductors and by the ground conductivity. The effect of wire size is slight. A sensible design criterion for an optimum ground system is attained by a suitable choice of the number and length of ground-wire radials so that they will always carry an appreciable fraction of the total earth current.[2]

A procedure for designing an optimum radial ground system which will assure l-f (below 1,000 kc) antenna efficiencies of 50 per cent or more provided the soil conductivity is accurately known is given below.[3]

Optimum design of the ground system, when the antenna and transmitter design are fixed, is accomplished when the total annual expense of such a system is at a minimum. This includes amortization cost of copper and its installation and the cost of the power

[1] See references 121 and 29.
[2] See reference 166.
[3] See reference 115.

dissipated in the ground. Copper costs are determined by wire diameter and spacing. If K_1 represents the annual cost of the copper wire and installation per meter, then K_1/d is the yearly cost per square meter of surface area, where d is the wire spacing. If C_a is the annual cost of station operation, C_b is the amortization cost of the station exclusive of ground system, and W is the average antenna input power, then $K_2 = (C_a + C_b)/W$ is the annual cost of operation per watt of antenna input power. If w is the power dissipated per square meter of ground surface with a conductor spacing d, then K_2w is the cost of the power dissipated in the ground. The power dissipated per square meter of ground surface is determined by the product of the square of the radial component of the surface current density J^2 set up on the surface of the ground by the antenna fields and the real part of the surface impedance of a square meter of soil (in which the conductors are embedded) in the radial direction. The total annual cost per square meter of ground system is the sum $K_1/d + K_2w$.
FIG. 17. Notations used in developing the optimum ground system.

The magnitude of the surface current density will decrease with distance from the antenna. At any point on the surface of the ground it is numerically equal to the tangential component of the magnetic field intensity at that point and, therefore, can be measured with a field-strength meter. Or, assuming a simple vertical radiator as shown in Fig. 17, the surface current density can be calculated from

$$\frac{\lambda J}{I_0} = j \frac{1}{2\pi \frac{r}{\lambda} \sin \beta_0 h} (e^{-j\beta_0 \rho} - e^{-j\beta_0 r} \cos \beta_0 h)$$

where I_0 = antenna base current
β_0 = propagation constant = $2\pi/\lambda_0$
λ_0 = free-space wavelength
ρ = distance from top of the antenna to point where J is to be determined
r = distance from base of the antenna to point where J is to be determined
h = height of the antenna

The magnitude and phase of $\lambda J/I_0$ for various antenna heights are shown in Fig. 18 as a function of radial distance from the antenna.

For l-f installations (below 1,000 kc) in nonferromagnetic ground of reasonable conductity (*i.e.*, $\sigma/\omega \gg \epsilon$, where σ = soil conductivity, ϵ = dielectric constant, and $\omega = 2\pi f$), the optimum wire spacing d which gives minimum total annual cost per meter of ground system can be determined from

$$d^3 \left(\log_{10} \frac{d}{2\pi a}\right)^2 = \frac{2.38 \times 10^8 K_1}{J^2 \sqrt{\sigma f^3}\, K_2}$$

where d = optimum wire spacing, m
a = wire diameter, m
J = magnitude of the surface current density, amp per sq m
f = frequency

Since the current density is a function of distance from the antenna, the optimum spacing, and hence total number of radials, will vary with distance. If we let F represent the right-hand side of the above equation, curve I of Fig. 19 gives a plot of the optimum spacing as a function of F for No. 8 AWG wire.

Having determined from Fig. 19 the conductor spacing at several distances r, the number of radials at any distance is given by $N = 2\pi r/d$. Usually the number remains substantially constant and permits selection of a fixed number close to the optimum for all spacings.

The optimum length of the radials can be obtained once the number of radials N is selected and the terminal spacing between conductors d_t is determined. Assuming the same conditions used to determine the above relation for the optimum spacing, the terminal spacing can be determined from

$$d_t^2 \left(\log_{10} \frac{d_t}{2\pi a}\right)^2 = \frac{1.88 \times 10^6}{f\sigma} = F_2$$
Fig. 18. Phase and density of radial ground current.
Fig. 19. Optimum and terminal spacing of buried conductors.

Curve II of Fig. 19 is a plot of d_t as a function of F_2 for No. 8 AWG wire. The optimum length of the radial is therefore

$$r_t = \frac{Nd_t}{2\pi}$$

26. Directive Broadcast Antennas. The allocation standards of the North American Regional Broadcasting Agreement pose some difficult design problems for new broadcast stations or those seeking power increases.[1] Most of these require directive antennas of varying complexity. Under the allocation rules, the limiting field intensities at particular azimuth and altitude angles, as determined by geography and wave

[1] See reference 136.

propagation, are calculated, and a directive antenna capable of performing within such limits must be found. A great deal of ingenuity and computational labor is involved in finding the specifications for an acceptable array.[1] To aid in this task, some calculating devices have been developed to shorten the work of cut-and-try approach for three radiators. The RCA Antennalyzer has helped solve pattern problems for two to five radiators in any azimuth, spacing, current amplitude, and phase relationship. With five radiators there are 16 independent variables that must be determined in strictly correct combinations. To do this, the Antennalyzer presents a horizontal pattern in either polar or rectangular coordinates on a cathode-ray oscillograph screen in correct azimuth. The dials are adjusted until a pattern is obtained that meets the limits necessary, and the specifications for the array are read directly from the dials. The pattern can also be made in rms form in a simple operation. Besides its value as an array synthesizer, this instrument is valuable in studying pattern stability problems, since tolerances in any variable can be quickly observed.

Without such an instrument, one proceeds the hard way to find an array giving a pattern meeting prescribed limits of protection and stability with the desired power.

27. Two-element Arrays. A wide range of broadcast directive patterns can be had using two vertical radiators by varying the tower-line azimuth, the spacing, the current ratio, and the phase difference.[2] Such patterns are symmetrical about the vertical plane through the radiators. A two-radiator directive system is the simplest that can be applied to directive broadcasting. Its pattern can be calculated from the equation

$$F(\theta,\phi) = f(\theta)(1 + k_1 e^{j\psi_1})$$

The legend for this equation is given later. For the case of $k = 1.0$ (equal radiator currents), the horizontal field-intensity patterns over a range of values of spacing and phase differences are presented in Fig. 20, which include the effects of mutual impedance. The reference circle in each diagram is therefore the relative field intensity for one radiator with the same power input.

28. Radiation Pattern for Generalized Multielement Array. If the conditions for applying pattern multiplication are satisfied,[3] the radiation pattern for an array of n identical vertical radiators whose ends are normal to a common plane (such as ground), as observed on the surface of an enclosing hemisphere whose radius is very large with respect to the greatest dimension of the array, is given in complex form as follows:

$$F(\theta,\phi) = f(\theta)(1 + k_1 e^{j\psi_1} + k_2 e^{j\psi_2} + \cdots + k_{n-1} e^{j\psi_{n-1}})$$

where $F(\theta,\phi)$ = relative field-intensity pattern in azimuth ϕ and polar angle θ
$f(\theta)$ = relative vertical field-intensity pattern for one radiator
k_m = I_m/I_0 and may be greater or less than unity
$e^{j\psi_m}$ = unit vector at an angle ψ_m with respect to reference vector
ψ_m = phase angle due to space and time differences

and

$$\psi_m = S_m \cos(\phi - \phi_m) \sin\theta + \alpha_m$$

where S_m = spacing in electrical degrees of radiator m with respect to radiator O
= $(360°/\lambda_0) \times$ physical spacing
α_m = phase difference between I_m and I_0; ranges through values of ± 180 deg
ϕ = angle measured clockwise from reference azimuth, usually true north
ϕ_m = azimuth of line through radiator m and radiator O and ranges clockwise through 360 deg

For the horizontal pattern only, $\theta = 90°$ and $\sin\theta = 1.00$. For the vertical pattern through any azimuth angle ϕ, $\cos(\phi - \phi_m)$ = constant.

Each term in this equation represents the phasor contribution of one of the radiators. When all radiators are located on a common line, the radiation pattern is symmetrical with respect to the vertical plane through this line.

[1] See reference 163.
[2] See references 39, 93, 119, and 149.
[3] See reference 9, Chap. 4.

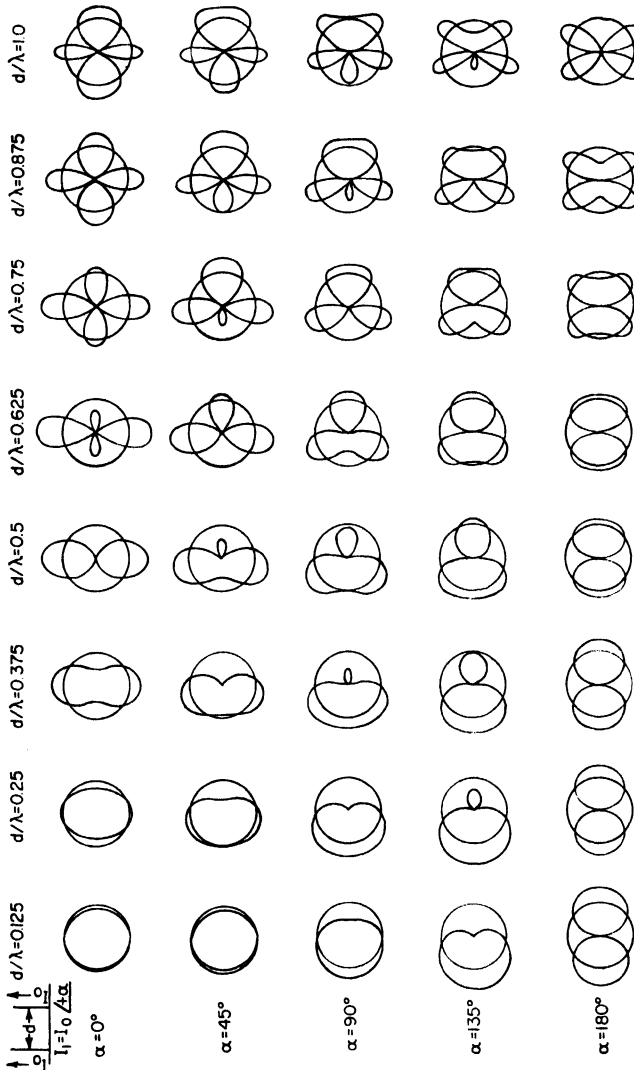
The rms value of a horizontal pattern can be obtained by measuring the area of the polar plot and constructing a circle of the same area.[1] If done in rectangular coordinates, the relative field intensities at each azimuth must be squared, then the area under the squared curve measured. The rectangle that has this same area on the same


FIG. 20. Horizontal patterns for two radiators fed with equal-magnitude currents taking mutual impedance into account. Circles indicate relative fields from one radiator alone with the same power input.

base then has its altitude squared to give the altitude of the rms field intensity for a single radiator with identical power input. From known performance of single radiators in terms of field intensity, power, and efficiency, the field-intensity scale in absolute values can be determined for the directional pattern.

[1] See reference 164.

29. An Exact Array-design Method.[1] The usual method of array design, which employs pattern multiplication, is an approximation which is sometimes adequate but which never predicts exactly the pattern of a practical array. Consider an array of identical antennas arranged in a uniform lattice. If pattern multiplication is applied, the pattern of the array is the product of an array factor, which depends only on the lattice arrangement, and the primary pattern, which depends only on the type of element used to make up the array. This procedure usually produces very good results when applied to arrays of dipole antennas. The error in this procedure is in the assumption that the radiation pattern of each element (when radiating in the presence of the remaining elements) is the same as the radiation pattern of an isolated element (when radiating in the absence of all other elements). This is never true in practice, although it may be very nearly true in certain cases. The distortion of the primary pattern of any element is caused by the scattering or diffraction of radiation by the other elements in the array.

An exact design method can be stated as follows. Let P_n represent the radiation pattern (amplitude and phase) obtained when unit current is injected into the terminals of the nth element and the terminals of all other elements are open-circuited. Let $I_0, I_1, I_2, \ldots$ represent the amplitude and phase of the currents flowing into the terminals of the elements when all the elements are energized. Then it follows from the principle of superposition that the pattern (amplitude and phase) of the array is given by

$$P = I_0P_0 + I_1P_1 + I_2P_2 + \cdots$$

In practice one would use pattern multiplication to obtain a first approximation to the array structure, build it, measure the amplitude and phase patterns P_n of each element in the presence of the entire array structure, and determine the distribution of currents $I_0, I_1, I_2, \ldots$ (by pattern superposition) which gives the best approximation to the desired array pattern. Usually this shows that the array could be improved by a small modification of the structure. When the structure has been fixed, the feed system can be designed according to the exact procedure and then the resulting array pattern will be exactly as predicted.

The exact method can be formulated equally well in terms of the patterns Q_n obtained when unit voltage is applied to the terminals of the nth element with all other inputs short-circuited.

If there is mutual impedance between the input terminals, the patterns Q_n will be essentially different from the patterns P_n; both P_n and Q_n will be affected by the location of the terminals. Thus where mutual impedance between the inputs is significant, one would try to select the position of the input terminals of the elements to make the functions P_n or Q_n as simple as possible. If the mutual impedance between terminals is insignificant, the patterns P_n and Q_n are the same, apart from a constant, and are independent of the loads connected to the unexcited inputs. However, these patterns in general will differ from the pattern of a single element with all other elements removed.

30. Feeder Design of Broadcast Arrays. The physical realization of a calculated directive antenna involves great skill in design and adjustment and great heed to accuracy of details. Through radiation couplings, any change in spacing, azimuth line for the radiators, current ratio, and phase difference of any radiator current reacts upon every part of the entire radiator and feeder system. Even with simple two-radiator systems, cut-and-try methods of adjustment are virtually hopeless. It is necessary therefore to predict accurately the conditions which must exist throughout the feeder system when working as desired and, by construction and careful measurement, to provide those conditions precisely. This naturally becomes more difficult as the number of radiators increases. In symmetrical systems there is a helpful simplification of work by dealing with radiators in pairs. The use of identical radiators of accurately known self-impedance and current distribution is particularly important as a starting point. For close-spaced radiators of the antifading type, the current distribution is modified by mutual coupling, which in turn modifies the expected feed-point impedances. Care must be exercised that guys on radiators do not measurably

[1] See reference 51.

deform the basic circularity of pattern for each radiator. Ground systems must present identical resistances in each radiator.

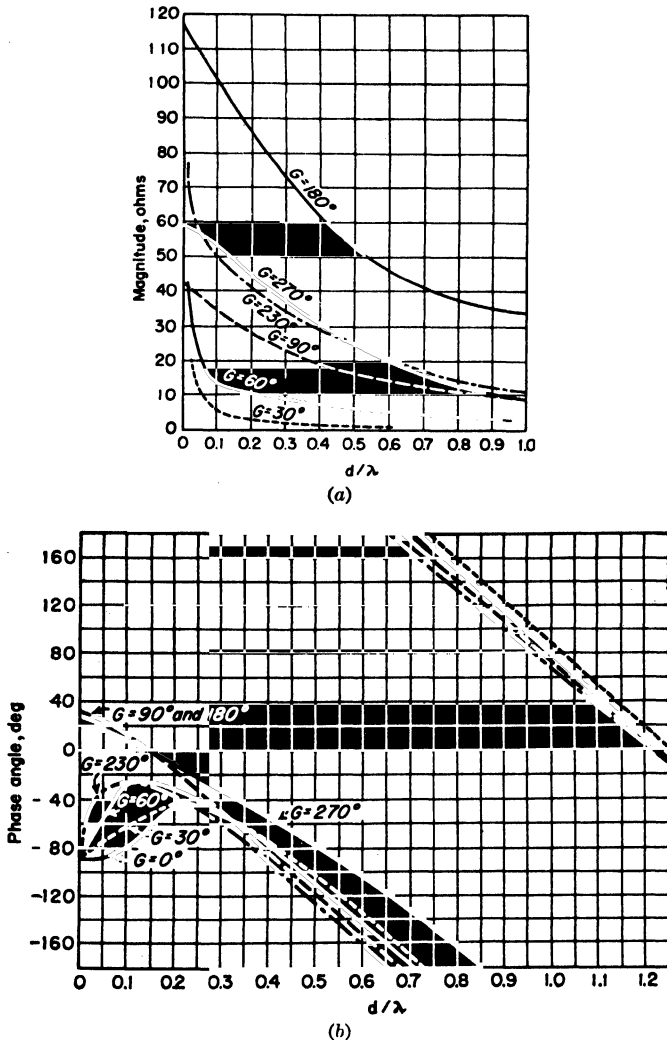
In designing a directive antenna system, the feed-point impedance of each radiator must be calculated for conditions which will produce the desired radiation pattern.


FIG. 21. (*a*) Mutual impedance between antennas. (*b*) Phase effect of coupled antennas.

This is done as follows. Let $Z_{00} = Z_{11} = \cdots Z_{mm}$ represent the self-impedance of an element of the array obtained from measurement of one prototype radiator at and about the working frequency, including base insulators, tower lighting devices, phase monitoring circuits, and any other attachments actually employed in final working status. However, identity of radiator impedances is not always assured by identical construction.

The transforming effect of all attachments to the radiator should be known as accurately as possible to be able to correct the mutual-impedance effects as transferred to the feed points, since the available mutual-impedance data are based on ideal conditions without such transforming effects present.

Measured values of Z_{00} (reference radiator) are then converted to their value *inside* the transforming devices. This then provides the idealized values of self-impedance.

Mutual impedances between all combinations of the radiators are then calculated or read from curves.[1]

The magnitude and phase of the mutual impedance between grounded vertical antennas of equal electrical height G are given in Fig. 21a and b as a function of antenna spacing d in wavelengths. The resistive and reactive components of the mutual impedance between vertical antennas of unequal heights located above a perfectly conducting ground assuming sinusoidal current distributions are shown in Figs. 22 to 25 as a function of antenna separation d for typical combinations of antenna heights.[2]
FIG. 22. Resistive and reactive components of mutual impedance between antennas of heights of 40 and 90 deg.
FIG. 23. Resistive and reactive components of mutual impedance between antennas of heights of 60 and 90 deg.

Simultaneous equations are then set up including the complex current relationships required in the various radiators, in the idealized location beyond the transforming effects:

$$
\begin{aligned}
E_0 &= I_0Z_{00} + I_1Z_{01} + I_2Z_{02} + \cdots + I_mZ_{0m} \\
E_1 &= I_0Z_{10} + I_1Z_{11} + I_2Z_{12} + \cdots + I_mZ_{1m} \\
E_2 &= I_0Z_{20} + I_1Z_{21} + I_2Z_{22} + \cdots + I_mZ_{2m} \\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\
&\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\
E_m &= I_0Z_{m0} + I_1Z_{m1} + I_2Z_{m2} + \cdots + I_mZ_{mm}
\end{aligned}
$$

The vector ratio of E_0/I_0, E_1/I_1, E_2/I_2, etc., for each radiator then gives the complex impedance (idealized) for each radiator. These impedances are then transformed back to the actual feed-point impedances (taking into account any phase shifts introduced by the transformation) for the several radiators.

Then the power input to each radiator must be calculated for the currents used in the previous calculation (based at this stage on current ratios) and the division of

[1] See references 32, 58, 59, and 119.

[2] See reference 25.

power among the several radiators determined. With power distribution known and also the feed-point impedances, the feed-system and the coupling-phasing networks can be calculated for each radiator and for the power-dividing networks. The designer has a wide latitude of choice in the arrangement of feeders, the type and characteristic impedance to use, and in the location of the power-dividing networks.

Owing to the fact that mutual-impedance vectors can lie in any of the four quadrants,[1] it is possible to find that, in some circumstances, the input impedance to a radiator has a negative resistance. This of course means that instead of feeding power into this radiator, a certain amount of power is delivered from the radiator into the feeder system. This is negative power from the standpoint of determining power division, and the feeder line must be terminated at the opposite end. Wherever possible to do so, it is desirable to avoid negative resistance inputs to radiators in the interests of system simplicity. However, in complicated arrays this may be unavoidable.
FIG. 24. Resistive and reactive components of mutual impedance between antennas of heights of 75 and 90 deg.
FIG. 25. Resistive and reactive components of mutual impedance between antennas of heights of 120 and 90 deg.

It is customary to terminate all feeders so as to suppress standing waves. Then the phase lag in a feeder is equal to its electrical length, which in turn depends upon the velocity of propagation in the lines used. If open-wire lines are used, the velocity is the same as that in free space. Enclosed lines always have velocity reduced in some degree, and this must be accurately known in order to use the electrical length of the line for the phasing calculations.

It is not necessary to suppress standing waves in the feeders unless they are so high as to cause appreciable power loss or high voltages. When not terminated, the line acts as a transformer, the input impedance is generally complex, and the phase lag for the line current is not the same as the electrical length of the line (see Fig. 26).

In a directive antenna it is the current that must have proper phase and amplitude. Thus, in the design of the feeder and coupling system, the current phases are to be controlled. Starting with the transmitter, the total phase difference to each radiator, the power-dividing networks, feeders, and coupling networks must be such as to bring to each radiator its correct relative phase and amplitude. Most of the networks

[1] See references 119, 58, and 59.

will have to make a specified impedance match with a specified phase shift, and networks must be individually synthesized on that basis.

When the system has been fully calculated and constructed ready for adjustment, the individual elements of each network are adjusted to calculated values at the working frequency with suitable measuring instruments.[1] Inductance adjustments must include external leads. After this operation, the network can be further verified by connecting an impedance across its output terminals equal to the anticipated working load and having its input impedance measured, trimming adjustments until correct input impedance is noted. Such trimming should involve only very small changes or
FIG. 26. Phase lag vs. line length for dissipationless line with resistive termination for various ratios of load resistance to characteristic impedance R_0/Z_0.

otherwise the phase-shift characteristics of the network may be incorrect even though the impedance transformation is correct.

When connected completely, the entire system can be energized with power, and the various currents in the system checked for amplitudes as a first test. If correctly calculated and measured, very nearly correct relative values should result immediately. Next, phases are checked by a phasemeter, or by the ultimate test, the measurement of the pattern. A first measurement of field intensity is made to determine that the nulls and minimums occur at correct azimuth angles. Careful circuit trimming ensues until the ammeters (previously checked for correct calibration) show correct relative values and the pattern nulls occur at correct angles.

Final test is to measure carefully the entire horizontal pattern at points of small enough azimuthal difference to provide full data in relation to the complexity of the

[1] See reference 119.

pattern. Measurements must be made on each angle to permit calculation of the unattenuated field intensity at some constant distance. For large arrays this may be the 2- or 3-mile circle, so that the pattern is fully formed. If the pattern is found to have the correct shape and orientation, power adjustments are then made for rated input, upon which basis the proof of performance is made.

31. Stability and Distortion in Directive Antenna Systems. Stability includes the effects of changes of the design parameters as well as the frequency. Many theoretical designs become impractical when viewed from the standpoint of stability. All system connections must be thoroughly secured and network-connecting leads held rigidly in their tested positions. Effects of corrosion, weather, deterioration, heating, etc., must be carefully anticipated to assure stability of adjustment for long periods. Networks should be placed in tamperproof locked boxes. With such precautions, directive systems maintain excellent long-term stability.

The impedance of a broadcast antenna, and particularly the common-point impedance of an array, often varies so much over the transmission band as to impair the frequency response, amplitude linearity, and modulation capability of the transmitter.[1] Recognition of this difficulty has led to the formulation of an EIA specification for the "normal load" into which a transmitter should operate and meet its performance requirements. This is a load whose resistance does not depart more than 5 per cent from its carrier-frequency value at ± 5 kc or 10 per cent at ± 10 kc, and whose reactance, which is zero at the carrier frequency, does not exceed 18 per cent of the carrier-frequency resistance at ± 5 kc or 35 per cent at ± 10 kc.

The results of measuring the side-band power, percentage modulation, and distortion of the signal delivered to a sharply tuned antenna system are considerably different at different points in the coupling system or along the transmission line. For example, if the variation in antenna impedance is equivalent to a series-resonant circuit at the carrier frequency, then under certain conditions of audio-input level to the transmitter (at a single audio frequency), the *voltage* at the antenna terminals (and any $\lambda/2$ back from the terminals) will appear to be fully modulated; that is, the magnitude of the two side-frequency voltages will be one-half the carrier voltage. But, because the impedance rises on either side of the carrier frequency, the side-frequency currents will be less than one-half the carrier current and an inspection of the current envelope would show less than 100 per cent modulation. The inverse is true at points an odd $\lambda/4$ from the termination. At points an odd $\lambda/8$ from the termination the impedance-vs.-frequency variation is dissymmetrical and both the voltage and current-modulation envelopes would appear distorted, and measurements at this point would indicate a high percentage of distortion in spite of the fact that no extraneous side frequencies are being radiated.

To determine actual delivered side-band power by measuring the current envelope, it is necessary to make the inspection and measurement at a point where the *series* resistance is independent of frequency over the band transmitted since it is the current squared times the resistance that determines power. These points occur every $\lambda/2$ from the termination. If the voltage envelope is to be monitored the point of measurement should be at a point where the *parallel* resistance is constant over the frequency band since the power in this case is the voltage squared divided by the parallel resistance. These points occur every odd $\lambda/4$ from the termination. In the first case, the maximum permissible modulation of the wave being analyzed has to be set by inspection of the voltage envelope at the odd $\lambda/4$ points, and in the second case, the modulation has to be set by inspecting the current envelope at $\lambda/2$ points. To permit plotting conventional curves of distortion vs. modulation frequency for particular percentages of modulation, it is necessary to express the percentage modulation in terms of the quantity (current and voltage) which can be allowed to attain full modulation at the monitoring point, even though the true side-band power, with sharply tuned loads, does not correspond to full modulation. There is justification for this in the fact that, when the maximum permissible modulation is reached, the power-amplifier tubes are

[1] See reference 129.

being required to deliver either full peak current or full peak voltage to the load, even if not both.

The point of connection of the power-amplifier tubes is of profound importance in the performance of the amplifier regardless of the circuit or modulation method used. Since one can ask only that a transmitter deliver a voltage or current wave free of phase modulation and having its envelope identical in shape to the audio-input wave, then only a point of impedance symmetry such as the $\lambda/2$ and odd $\lambda/4$ points is appropriate for making connection to the tubes. If envelope feedback is used only the odd $\lambda/4$ points are satisfactory.

The design of a variable-phase shifter or *line stretcher* with a total range of about 180 deg for use in broadcast transmitters to obtain the required impedance-vs.-frequency characteristics is shown in Fig. 27. In this figure $\omega L_1 = \omega L_2 = R$ = terminating resistance, $\omega C_1 = \omega C_3 = [1 - \cot(\Phi/2)]/R$, and $\omega C_2 = 2[1 - (\sin \Phi)/2]/R$, where Φ is the desired phase shift. In some cases it can be inserted between the r-f plate terminal of the power amplifier and the transmission-line matching section. This network has good harmonic-suppression characteristics.
FIG. 27. Phase shifter for use in broadcast systems.

In addition to the signal distortion introduced by the frequency selectivity of the antenna input impedance, a second type of distortion can result from the directional characteristics of an antenna array.[1] For example, the directional pattern of an array is a function of the transmitted frequency, and can be different at the side-band frequencies from that obtained at the carrier frequency. These radiation-pattern differences cause changes in the relative magnitudes and phases of the signal components and hence cause distortion of the modulation envelope. At low audio-modulating frequencies the directional properties of the pattern for the carrier-frequency and the side-band-frequency components are essentially identical. However, at high audio-modulating frequencies and relatively low carrier frequencies the pattern band width for a particular directional characteristic may be sufficiently narrow as to result in severe changes in the relative amplitudes and phases of the signal components. In the null direction, for example, the carrier signal may be completely canceled, but a side-band component may reach reinforcement. In the directions of maximum carrier signal the converse conditions are likely to occur, resulting in reduced high-frequency side-band power.

Arrays of many elements, high-Q tuning networks, negative power elements, and deep nulls are more likely to exhibit severe antenna distortion than simpler, lower-Q antenna systems. Deep nulls should be avoided if service is to be rendered in the null directions.

32. Half-wavelength Bent-wire Antenna.[2] There are other services besides a-m broadcasting that use the m-f band. Some of these services can use broadcast-antenna designs, but for others, wire antennas are more practical. A simple yet effective method of obtaining a high radiation resistance at the feed point of a grounded vertical antenna is shown in Fig. 28. The horizontal section should be $\lambda/4$ long so that a current maximum will appear at the top of the vertical section. Since the most useful radiation takes place from the vertical section at these frequencies, it should be as long as possible, preferably $\lambda/4$. In any case, the horizontal section should be $\lambda/4$ long.

FIG. 28. Half-wave bent-wire antenna.

A parallel-resonant coupling circuit should be used if the vertical section is greater than about $\lambda/8$. For vertical lengths less than $\lambda/8$ a series-resonant coupling circuit should be used.

[1] See reference 156.
[2] See reference 3.

Antennas of this type offer an opportunity for using a simple feeder system that permits installing the antenna some distance from the transmitter. If the vertical section is $\lambda/8$, for example, the total radiating length is $3\lambda/8$. An additional $\lambda/8$ may be added to the antenna to make the total length $\lambda/2$. This additional length is used as the feeder and hence should run parallel and close to the ground to reduce the radiation from it. A parallel-resonant coupling circuit should be used between the input end of the feeder and ground.

In all cases the distance between the coupling circuit and the effective ground should be only a few feet. These leads are part of the effective length of the antenna, and must be added to the antenna length in determining the constants required in the coupling circuit.

Since ground-wave propagation or low-angle radiation for sky-wave propagation is of prime importance at these frequencies the vertical portion of any top-loaded vertical antenna system should be as long as possible. The horizontally polarized radiation from the horizontal section of the antenna occurs at high angles and contributes essentially nothing to the ground wave, and in the daytime the sky wave is absorbed by the ionosphere. At nighttime, however, this horizontally polarized sky wave is reflected with little attenuation. Horizontally polarized radiation from the bent-wire antenna, for example, can be minimized by folding the horizontal section back on itself.

33. Antennas on Ships. Ships of all sizes, with their masts, rigging, derricks, etc., severely circumscribe the antenna designs which can be used. As time goes on, more and more antennas are needed for new radio services on ships. There is usually the "main" antenna for l-f transmission and reception, one or more h-f antennas, a sense antenna for the direction finder, an antenna for the ship's broadcast receiver, and occasionally others for special uses. Their disposition depends largely upon the architecture of the ship and the location of the various facilities and operating rooms. They are located wherever space can be found.

The main antenna is usually a single-wire inverted-L or T antenna suspended between the main masts. Being electrically short at the lowest working frequencies, there is a rather high potential on the system when used with medium- and even low-power transmitters. Therefore, the insulation must be electrically and mechanically robust throughout its length and through the deck bushing to the transmitter. This antenna is often used also for h-f service, in which case the system is electrically very long and provides a many-lobed pattern with vertical and horizontal polarizations. The random radiation patterns obtained provide the necessary functions for communication. The same is essentially true for the single-wire antennas installed for h-f duty only.

The sense antenna for use in conjunction with the direction-finder loop antenna is as nearly vertical as can be and terminates at the d-f location.

As a consequence of typical shipboard circumstances, there is little or no electrical designing possible in the sense in which it is applied to types of land services. There are important mechanical design considerations to be met to withstand the severe weather encountered at sea.

34. Antennas on Aircraft. Only a few elementary remarks will be made on this complicated subject, and these apply to the simplest applications on private and transport aircraft. The characteristics of aircraft antennas are largely empirical, depending upon the frequency, the size and shape of the aircraft, and the available locations. For slow flying speeds, fixed antennas are the rule and so disposed as to offer a minimum drag during flight. Thus antennas are generally oriented parallel to the slip stream over the fuselage (for l-f and h-f services) from a short mast over the cockpit to the tail structure, and under the fuselage for the 75-Mc marker antennas. Vibrational stress is severe, and precautions must be observed in choice of material and method of rigging to sustain typical conditions. At the frequencies where the antenna has high reactance and low resistance, a few watts of antenna power produce very high potentials, which, with high altitude, easily give rise to corona and flashover. Corona formation in high-velocity air occurs at higher potentials than in still air. Care is

required to avoid sharp points which accentuate discharge, and the conductors should be as large as possible. Insulated antenna wire raises the corona potential and also reduces precipitation static.

Direction-finder loops are sometimes fully exposed in low-speed ships, enclosed in streamlined envelopes for medium-speed ships, or located inside the nose of the ship behind a dielectric envelope. To reduce the size of exterior loops and thus decrease drag for exterior loops, powdered-iron cores can be used. When two loops are used with automatic direction finders, exterior mounting is usually necessary.

For instrument landing, both localizer and glide-path antennas are usually located somewhere near the cockpit or the radio room. For v-h-f operation these are presently small horizontal single-turn fixed loops with balanced outputs to the equipment. Vertically polarized v-h-f communication equipment often uses a short whip antenna. U antennas can also be applied to v-h-f reception of horizontal polarization. Flush-mounted antennas are required for high-speed and supersonic aircraft and missiles. Practical flush-mounted u-h-f and s-h-f antennas have been developed for this service and are described later in this chapter.

Radio altimeters employ a pair of electric-dipole antennas, one located under each wing with the dipole parallel to the slip stream. Careful streamlining of the antenna is required for this application, and a spacing insulator is used at the center for mechanical rigidity.

Trailing wire antennas are impractical for high-speed aircraft unless they are very short. A trailing wire v-h-f antenna, with coaxial transmission line and a coaxial dipole antenna at its end for the antenna and feeder system from the rear of the ship, may be used in some circumstances. For private aircraft, a prevailing type of h-f trailing antenna passes from the antenna reel through a guide at the top of the tail structure, and is held out in the slip stream by a small wind sock at its end. When reeled in, this antenna is secure and obscure.

H-F ANTENNAS (3 TO 30 MC)

35. Straight Horizontal Half-wave Dipole. A straight conductor parallel to earth, of the order of one-half wavelength long, suitably excited, is one of the most elementary and useful h-f radiating systems. When exactly $\lambda/2$ long, and in free space, a thin wire antenna has a center-point impedance of approximately $73 + j30$ ohms. When placed parallel to and within about 5 wavelengths of ground, mutual impedance with its image causes the impedance to vary appreciably with its height. Figure 29 shows how the radiation resistance varies with height for both horizontal and vertical half-wave dipoles.[1]

The electric field around a $\lambda/2$ dipole resembles that of the magnetic field of force around a short bar magnet. When in free space, the pattern factor at constant distance follows the relation

$$F(\theta) = \frac{\cos(90° \cos\theta)}{\sin\theta} \qquad (\theta \text{ measured from wire})$$

from which it can be seen that there is zero field intensity in the direction of the dipole and maximum everywhere at right angles to it. It is therefore a directive radiating system. In practice and when used over ground, some endwise radiation occurs because of reflections from ground and from the ionosphere, and in this direction the field is vertically polarized. Normal to the wire the field is horizontally polarized. In intermediate directions there are components of both.

In h-f applications the most important characteristic of such an antenna is its vertical-plane pattern normal to the wire. Over perfectly conducting earth, this has the equation (origin at dipole above ground)

$$F(\phi) = \cos(H \sin\phi \pm 90°)$$

[1] See reference 32.

When the complex reflection coefficient of the ground is taken into account, the equation becomes

$$F(\phi) = 1 + Ke^{-i2H \sin \phi}$$

where $F(\phi)$ = relative field intensity as a function of elevation angle ϕ
H = electrical height of antenna above ground = $2\pi h/\lambda_0$
K = complex reflection coefficient for horizontal polarization and is a function of soil conductivity σ and inductivity ϵ, the angle of incidence ϕ and the frequency f, derived from the equation

$$K = \frac{\sin \phi - (\epsilon^{-i2\sigma/f} - 1 + \sin^2 \phi)^{1/2}}{\sin \phi + (\epsilon^{-i2\sigma/f} - 1 + \sin^2 \phi)^{1/2}}$$

The phase angle is always 180 deg in this case.
FIG. 29. Radiation resistance vs. height.

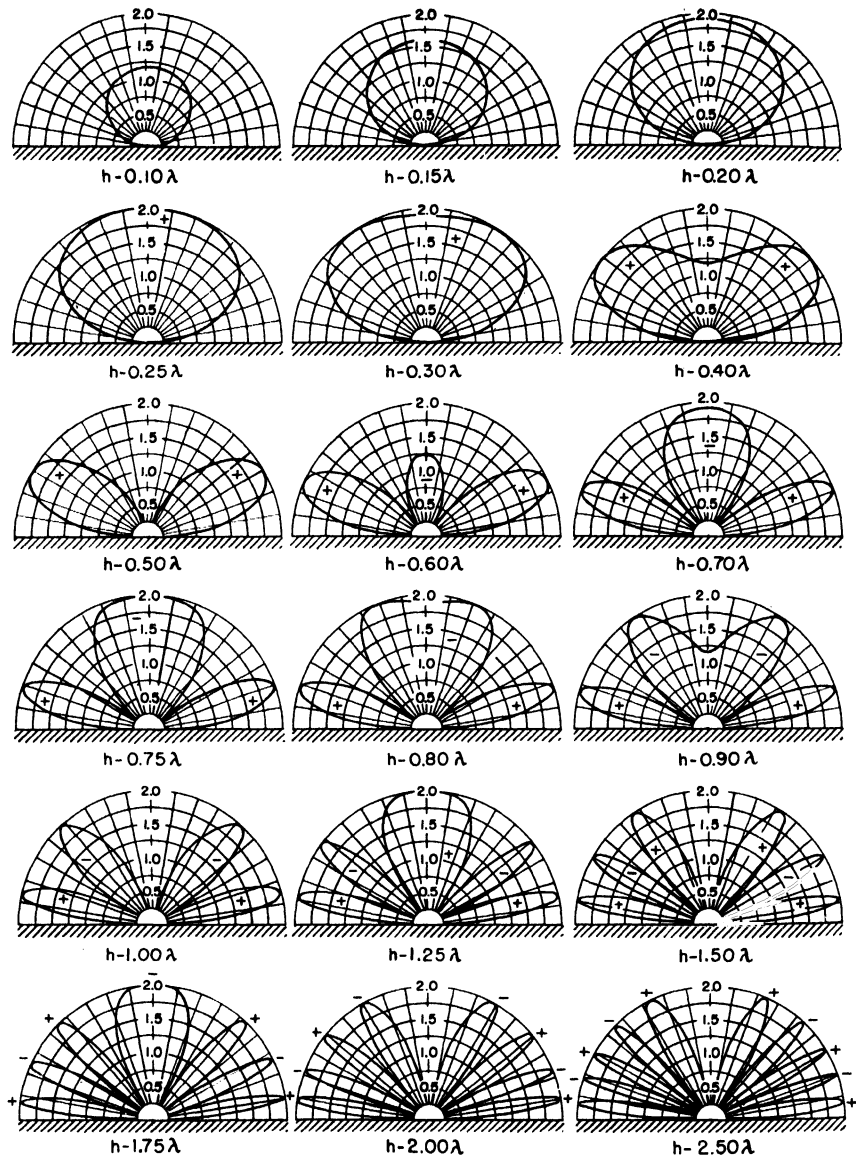
For perfectly conducting ground (hypothetical), $K = 1$. Figure 30 shows a series of these patterns for various heights h up to $2\frac{1}{2}\lambda$. The relative polarity of the field in each lobe is indicated. Figure 31 charts the angles of the maximums and the nulls for these patterns. These angles are important for propagation purposes. Figure 32 exhibits the optimum radiation angles for propagation via the various ionosphere heights as functions of distance for one-hop transmission.


FIG. 30. Vertical polar diagrams for horizontal dipoles.

Both transmitting and receiving antennas of this type, used over fixed circuits, should be at the same height and perpendicular to the direction of transmission.

36. Feed Systems. The straight half-wave dipole can be center-fed in series from a balanced feeder, or shunt feed (also called delta- and Y-feed).[1] The shunt-feed system, when correctly performed, makes a satisfactory impedance match directly

[1] See reference 32.
Fig. 31. Angles of maximums and minimums, horizontal dipole.
Fig. 32. Optimum radiation angle for propagation for one-hop transmission.

(but never perfectly, unless series capacitors are included to correct for the inductive effect of the enclosed portion of the antenna) for low standing-wave ratio on the feeder. Care must be taken to maintain exact symmetry of connection between line and antenna. Adjustments for this are shown in the upper part of Fig. 29.

Feeders should always run normal to the antenna wire for as far as possible from

the antenna, and skew relations avoided wherever possible. Skew relations cause radiation couplings between feeder and antenna which upset line balance and compromise pattern and efficiency. This is quite general and should be observed in all antenna designing.

Instead of spreading the feeder to make an impedance match, the dipole can be shortened and a small inductance inserted between the junctions with the feeder. The latter is run at fixed separation directly to the antenna. A compromise match can be made in this way, in which case the antenna is then known as a *shortened dipole*. Its advantage over the simpler arrangement preceding is nil, and the operation of adjusting is more difficult.

Another feed method, technically inferior but often used for its simplicity, is off-center feed, with a one-wire feeder, working against ground.[1] A position can be found on the antenna where standing waves on the feeder are quite small for one frequency.

Transformer coupling between feeder and antenna can also be used but there is no good reason to do so.

Both the input impedance and the current distribution (and hence radiation pattern) of dipole antennas (from $\lambda/2$ up to 3 to 4λ long) depend upon the location of the feed point as well as the over-all length of the antenna.

The current distribution on linear-dipole antennas is the sum of attenuated traveling waves influenced by mutual coupling between its arms and its image if located above ground. For thin short dipoles, the distribution is essentially sinusoidal, while for thick and/or long dipoles the distribution is essentially a traveling-wave distribution. This is evident from the radiation patterns.[2] The effect of feed location and antenna length and thickness on the input impedance and radiation pattern can be found in the literature.[3]

It is possible to feed an antenna at a current loop not necessarily at the center. The impedance will be higher at these loops. The so-called "Windom" antenna is a half-wave dipole fed off center with 300-ohm line and as such works well at the higher harmonics of the wire. The SWR will be higher than when fed with 72-ohm line at the center, but if the leads of the transmission line are closely spaced, as with 300-ohm Twinlead, the radiation from the line will be low.

Another type of all-wave antenna is a shortened dipole with tuned *LC* traps inserted each side of the center at such a distance that the center portion is resonant at the second harmonic. The traps are tuned to this harmonic frequency. Such a system will operate with low SWR on all harmonic frequencies of the fundamental.

37. Radiated Field Intensities of Dipole. In free space, maximum field intensity at 1 mile (d = 1,610 m) with 1,000 watts radiated from a $\lambda/2$ dipole is 138 mv per m. Owing to ground reflections, pattern maxima vary from one to two times this value depending upon height and ground reflectivity.

38. Selectivity and Band Width. The selectivity of a $\lambda/2$ dipole is maximum for thin wires where it can be considered to have a band width of the order of ± 1 per cent of optimum frequency. Where larger band widths are to be transmitted quite uniformly, the ratio of diameter to length of one-wire or cage antenna should be the largest practicable. If propagation considerations permit, the heights should be made such as to give maximum radiation resistances, as shown in Fig. 29. Where band widths in excess of ± 5 per cent in frequency are required, other types of construction should be used such as folded dipoles.

39. Antenna Potentials. Where high power is to be transmitted, or at high altitudes, antenna insulation and conductor designs require heed to details. For h-f use, only radial potential gradients need be considered. At high altitudes, pluming may occur with consequent damage to the system. Fortunately in practice, high power is generally used with directive antennas, and the power is divided among several

[1] See reference 200.
[2] See references 9 (Chap. 9) and 199.
[3] See references 196 and 226.

dipole sections, thus tending to minimize this problem. A thin-wire dipole gives an end potential of about 3,900 volts rms for 1,000 watts antenna input for a height of 0.25λ. It will be higher for smaller heights, and falls to a minimum of about 1,700 volts as height increases to 0.75λ; beyond this point it settles down to the free-space value of about 3,000 volts. Potentials vary as the square root of the power ratio and as the inverse square root of the capacitance per unit length. For a potential of 3,900 volts on a wire 0.101 in. in diameter (No. 10 B&S), the radial gradient is of the order of 31 kv per cm. As a rough approximation for a cage, the gradient for one wire is divided by the number of wires in the cage.

40. Half-wave Dipole for Receiving. In receiving, one wishes to know the receiver input voltage when the receiving antenna is immersed in a plane wave field of E volts per m when both the antenna and the receiver are correctly matched to a feeder of known characteristic impedance Z_0. This can be approximated in the following manner:

The area over which a $\lambda/2$ dipole collects energy is 0.1305 square wavelength.[1] The power density within this area from the field is $P = E^2/377$. If the antenna is in free space and has no losses, the power intercepted would be, for optimum antenna orientation,

$$W = \frac{0.1305\lambda^2 E^2}{377} \qquad \text{watts}$$

so that the receiver input voltage would be

$$V = \sqrt{\frac{W}{Z_0}}$$

Over ordinary ground we may estimate that the effective area with the image might be about 1.9 times that in free space. Mismatches in the system, together with other losses, probably would yield a net value approximately the same as for the free-space condition given above.

For a mismatch at the receiver, producing a standing-wave ratio of Q, the net receiver input power $W_r = 4WQ/(1 + Q)^2$.

41. Double-dipole Antenna. Two dipoles end to end and connected to the two wires of a balanced feeder provide a very useful antenna for simple directive applications. The dipoles may be of arbitrary length, but for fixed frequency working are usually $\lambda/2$, or for greater directivity, $5\lambda/8$. The currents in both dipoles are then cophased, producing maximum radiation normal to the antenna. Its vertical pattern in that plane is the same as a single dipole.

The gain of Fig. 33*a* is 1.8 db over a single $\lambda/2$ dipole, and the gain for Fig. 33*b* is 2.8 db. In this figure only one half of the pattern is shown.

When series-fed at the center and allowing standing waves on the feeder with suitable impedance-matching circuits for coupling to the radio equipment, this antenna will accommodate a wide range of working frequencies while directing the maximum field along the normal to the antenna. Each side is made $5\lambda/8$ at the highest working frequency. As the frequency is lowered, the electrical length of the radiator decreases, the radiation resistance decreases, and the pattern broadens in azimuth. Where a single antenna must be used for several working frequencies, accepting the random variations in the vertical pattern as a compromise, this design is very useful.

42. The Lazy-H Antenna. This system is a combination of two double dipoles (Fig. 34) one above the other, separated $\lambda/2$ and voltage-fed. The horizontal pattern is the same as for a single double dipole, but the vertical directivity is increased by the use of the second set. This, in combination with the effects of height, provides a variety of useful beams which can be focused in the direction and vertical angle required by the propagation conditions. The currents in all four dipoles are cophased by the transposition in the feeder between the upper and the lower radiators. The

[1] See references 40 and 279.

vertical pattern normal to the radiators when over perfectly conducting earth is

$$F(\phi) = \cos\,(H^\circ \sin \phi + 90^\circ) + \cos\,[(H^\circ + 180^\circ) \sin \phi + 90^\circ]$$

where H = electrical height, deg.

Fig. 33. Double dipoles and approximate patterns.

Fig. 34. Lazy-H antenna.

This is the arithmetic sum of the vertical pattern for the upper radiator, added, angle for angle, with the pattern for its image. In performing this addition, the polarity of the field of each lobe must be correctly included.

In free space the gain of this array is 3.95 db over a single dipole. When a plane reflecting screen is added to make it unidirectional, spaced 0.1λ parallel to the antenna, the gain can be increased by another 4 to 6 db depending upon the area of the screen.

The same principle can be used for a vertical-H array for vertically polarized transmissions.

Taking into account the actual ground reflectivity, the vertical pattern is best expressed by

$$F(\phi) = 1 + e^{jS \sin \phi} - Ke^{j(S+2H) \sin \phi} - Ke^{j(2S+2H) \sin \phi}$$

where S = electrical spacing between upper and lower radiators
H = electrical height above ground of lower radiator
K = amplitude of reflection coefficient of ground

Unidirectional transmission is obtained when a close-spaced reflector grid is placed on the blind side of the system.

43. Vertical Antenna. Vertical $\lambda/2$ dipoles are not much used for h-f services. In the past, most uses of vertical dipoles have been where the uniform omnidirectional radiation property was of prevailing importance, but quadrant antennas may be used for this purpose. Vertical polarization for short and medium distances from low altitudes and over sea water is often required, and the vertical $\lambda/2$ dipole can then be employed advantageously. A loaded vertical antenna less than $\lambda/2$ is frequently used as a vehicular antenna[1] (see Sec. 19, whip antennas).

Its vertical field-intensity pattern varies with its height. The pattern function for a $\lambda/2$ vertical dipole over perfectly conducting earth is

$$F(\theta) = \frac{\cos (90^\circ \cos \theta) \cos (H \cos \theta)}{\sin \theta}$$

where θ is the angle with respect to the antenna and H is the height in electrical degrees of the current maximum, above ground. At h.f. the complex reflection coefficient from earth or water causes a mutilation of this ideal pattern. The very low angle intensity is greatly reduced, especially along the ground. This emphasizes another important consideration with all vertical h-f and v-h-f radiators—the nature of the earth out to considerable distances from the radiating system. The performance of identical antennas in different locations may vary greatly owing to earth differences. In the immediate vicinity of the radiator, this can be beneficially controlled by the use of a radial system of elevated, surface, or lightly buried ground wires having a length of the order of $\lambda/2$. The greater the distance between the lower end of the radiator and the earth, the smaller the importance of the wire system in reducing system losses, and the greater should be its length if used.

44. Feeding a Vertical Dipole. The most convenient method of feeding a vertical $\lambda/2$ dipole is at its lower end which is a voltage antinode. A voltage feed method is therefore necessary. If a balanced feeder is used, a line arrangement of transforming from balanced to single-end and to high standing-wave potential is required. One method is to run the open-wire balanced line past the antenna $\lambda/4$ and short-circuit it. The antenna is then connected to one side of this line $\lambda/4$ from the short circuit. This sets up a very strong standing wave in the feeder and equalizes the unbalance introduced by feeding from one wire only. Some distance toward the transmitter the feeder is terminated with a stub line inductance or coupled matching section. In some cases the system can be fed without impedance matching if line losses can be tolerated and the input impedance is of a value that can be accommodated by the transmitter coupling. If the antenna is elevated, the feeder wires rise to the height of the lower end of the antenna and one wire connects to the antenna end and the other remains open-circuit. The unbalance caused in the feeder can be corrected at some convenient point and terminated at another point. Center feed for a vertical dipole is mechanically difficult, but when used, the feeder should be as nearly normal to the antenna as realizable to avoid large unbalance of the feeder. In general, end feed is preferred.

Vertical antennas for direction-finding stations are usually shorter than $\lambda/2$ at the highest frequency, are rigidly held in place near ground, and have extensive radial

[1] See reference 3, p. 282.

ground-wire systems for each antenna, so as to minimize wave tilt in the vertically polarized field component used for direction finding.

45. Folded-dipole Antenna.[1] This radiator is virtually a $\lambda/2$ dipole, a cage, and an impedance transformer built into one unit. H-f types made of wires are exemplified in Fig. 35. As a radiator it functions like an ordinary dipole, giving the same patterns, but with transformed radiation resistance and reactance at the feed point. Greater cross-sectional area due to folding gives it wider band-width characteristics for a given deviation in impedance, and reduces potential gradients and end potentials, for a given input power. Impedance transformations due to mutual impedances between the wires and due to their lengths make it possible to provide exact match with ordinary open-wire balanced feeders. A variety of combinations of wire sizes, spacings, lengths, and foldings are possible for specific applications, and single-end as well as balanced versions can be designed for h-f, v-h-f, and u-h-f uses.[2] For a two-wire folded dipole the factor is 4, and for the three-wire system it is 9 times the radiation resistance for a single-wire dipole. The antenna impedance can be made to match the feeder by choice of spacing and wire size, height, and length. In general, for a folded $\lambda/2$ dipole of N wires of equal diameter, the terminal resistance is approximately $70N^2$ ohms.

FIG. 35. Folded-dipole antennas. Resistances shown are due to height above ground.

The stepup impedance ratio U of a two-conductor folded $\lambda/2$ dipole antenna is given as a function of the conductor radius and spacing by[3]

$$U = (1 + a)^2$$

where

$$a = \frac{\cosh^{-1}\left(\frac{d^2 + \rho_1^2 - \rho_2^2}{2d\rho_1}\right)}{\cosh^{-1}\left(\frac{d^2 - \rho_1^2 + \rho_2^2}{2d\rho_2}\right)}$$

d = center-to-center spacing

ρ_1 and ρ_2 = radii of the two conductors ($\rho_2 \geqq \rho_1$)

[1] See reference 265.
[2] See references 212, 223, and 3.
[3] See reference 226.

The feed point is located at the center of the smaller-diameter conductor.

A three-wire cage 10 in. in diameter has a band width of ±7 per cent from optimum for a maximum of 2:1 standing-wave ratio on the feeder.

46. Quadrant Antenna (Fig. 36). The quadrant antenna[1] consists of two radiators lying in a horizontal plane and mutually perpendicular from a common apex. Each radiator has a nominal length of 0.45λ for single-frequency use, or for the mid-band frequency when designed to obtain wide-band characteristics of approximately 2:1. Its principal feature as a radiator is its omnidirectional radiation pattern for horizontally polarized fields, as distinguished from a straight antenna. The horizontal field-intensity distribution for the latter varies approximately as the cosine of the angle to the wire, whereas with the quadrant antenna the pattern is virtually square with broadly rounded corners. The wide-band arrangement is often desirable either for eliminating antenna tuning over a 2:1 range or for the transmission of signals requiring great band width. At the extremities of the 2:1 frequency band, the pattern changes from an oval with major axis along the bisector of the quadrant and having an eccentricity of about 1.8 (lowest frequency) through the near-square pattern at mid-frequency to a quadrilobe pattern with a maximum to minimum ratio of about 1.5 at the highest frequency.

Fig. 36. Approximate horizontal field-intensity patterns for wide-band cage quadrant antenna at high, mid-, and low frequencies.

The broad-band characteristics are derived from the use of large-diameter cages having low characteristic impedance. For single-frequency operation, a single-wire design is used. The vertical pattern is determined by the height above ground just as for a straight dipole.

The quadrant antenna is fed at its apex by a balanced transmission line having characteristic impedance between 400 and 600 ohms, depending upon particular designs. Four such antennas, properly proportioned, can be used to cover the h-f band in 2:1 steps, and these can all be assembled on four supports. Identical arrangements may be used for transmitting and receiving.

47. Extensive Dipole Arrays. The H antenna is the basic form for flat arrays of dipoles which can be extended as far as desired in height and width to achieve a high degree of radiation control in vertical and horizontal planes. In the same manner, arrays can be made with dipoles in depth in any degree, in what are called *cubical arrays*. In practice, cubical arrays have found almost no use because of the complications of construction. Unidirectional patterns have been mainly obtained by placing a duplicate sheet of dipoles behind the main sheet and exciting the reflector parasitically or directly.[2] The adjustments of the reflector elements differ somewhat for the two conditions. Another, simpler method is to use a close-spaced neutral reflector sheet of area somewhat larger than the radiator sheet made up of wires spaced 0.05 to 0.1λ parallel to the radiating dipoles. The closeness of spacing of the reflector wires primarily determines the magnitude of the backward radiation, and the forward radiation is but slightly increased for wire spacings smaller than 0.2λ.

Through the years a great number of distinctive beam-antenna designs have appeared and disappeared. It would be possible to describe numerous ingenious forms developed in the great era of h-f growth from 1923 to 1932. In the interim,
[1] See reference 237.
[2] See references 188, 197, 198, 207, 218, and 232.

economics and the virtual abandonment of vertical polarization for long-distance h-f communications took their toll of all but a very few basic forms which are considered here in some detail because of their importance, technically and economically. It is interesting to note that evolution has shown the absurdity of paying a high price for an extra decibel of gain when the medium of propagation varies many hundreds to one. This variation in the medium has also obscured the very poor performance of many antenna designs. Multipath transmission places a limit on the speed of keying and on speech mutilation on very long circuits. Greater control of the vertical patterns for transmitting and receiving antennas can effect improvements by angular discrimination between various orders of hops with various delays. Owing to multipath delays, the working speed decreases as circuit lengths are increased. On very
FIG. 37. Arrays of horizontal half-wave dipoles and typical feeder connections.

long circuits, a fundamental limitation exists where the two or three lowest orders of hops come within angles which overlap those due to variation in layer height, and against which angular discrimination is impossible. In such cases the only solution seems to be to use intermediate automatic relays.

The flat array of horizontal dipoles (the *pine-tree* or *Koomans array*) is a basic type which provides independent control of vertical and horizontal patterns.[1] The V and rhombic types have these two properties interrelated.

4W4H and 6W4H arrays are shown schematically in Fig. 37. Dipoles are each $\lambda/2$ and spaced $\lambda/2$. Diagram *a* shows two feedlines, the array being two sets of four cophased double dipoles. This feeding method gives equal currents in all dipoles at one level, and there is a slight reduction in currents vertically due to attenuation along the feeders. At *b* is a common-feeder system with three dipoles in series, cophased by the $\lambda/4$ phasing sections between colinear dipoles. Cophasing between levels is by transposition of the feeder. Identical arrays could be used as reflectors, or a neutral sheet reflector employed.

In a multifeeder system as in *a*, the two sections of the array can be mutually dephased by a small amount to slew the beam a few degrees for different circuits with small angular path difference.

The horizontal pattern function for an array of *n* colinear cophased dipoles arranged in *m* symmetrical dipole pairs from the feeder is given approximately by

$$F(\theta) = \frac{\cos(90^\circ \cos\theta)}{\sin\theta} \sum_{m=1}^{n/2} I_m\{\cos[(2m-1)90^\circ \cos\theta]\}$$

[1] This is only approximately true because of the mutual coupling between elements. However, in most practical arrays it is a good approximation. See reference 51.

where the coefficient is the pattern for a single dipole, and each term in the series is the pattern for an isotropic source located at the center of each dipole pair symmetrically from center (feeder) and having an intensity proportional to its loop current. Azimuth angle θ is measured from the line of the radiators. This pattern can be expressed in many other forms, but this one permits the use of current-grading coefficients as well as the usual equality of currents.

The vertical pattern for an array of k vertical elements can similarly be obtained from the following equation, where each level of radiators forms a pair with its image but with image current reversed.

$$F(\phi) = I_1 \cos (H \sin \phi + 90°) + I_2 \cos [(H + 180°) \sin \phi + 90°] + \cdots + I_k \cos \{[H + (k - 1)180°] \sin \phi + 90°\}$$

At an elevation angle ϕ, with a height H deg between ground and the lowest radiator with current amplitude I_1, the first term will be the pattern for this first level. Other levels have patterns according to the successive terms at successive heights differing by $\lambda/2$. If other than $\lambda/2$ vertical spacing is used, the actual spacing is substituted for 180 deg in this equation. This equation is adapted to the use of vertical current grading by assigning proper values to I_k. Actually to grade the currents, the feeder line must act as an impedance transformer while retaining its proper phase relations at the various radiator levels.

For identical currents in all dipole elements, the maximum field-intensity gain due to directivity is proportional ideally to the square root of the number of dipoles used, in both radiator and reflector curtains. With neutral reflectors, the radiator images are counted. A number of factors cause an appreciable impairment of this ideal gain, among them ground losses, insulation losses, imperfect phase differences, reflections from discontinuities or irregularities, conductor losses, losses in associated rigging and supports, etc. A well-constructed system may be 2 to 6 db below expectation depending upon size, frequency, and location.

In constructing such a system, all conductors are cut from 5 to 10 per cent shorter than theoretical length based on a velocity of propagation equal to that in free space, to allow for effects of corner junctions, insulator capacitance, and end effect.

48. Tuning Dipole Arrays. The tuning of an array using a tuned reflecting sheet is very difficult because of mutual impedance relationships, which cause very strong interactions between radiators and reflectors. When the reflector is excited parasitically, it must be quite close to the radiator sheet to have best effectiveness. The complex nature of mutual impedances causes the spacing and adjustments to be different for maximum forward radiation as compared with minimum backward radiation. To reduce this tuning difficulty, some systems have used a radiator-reflector spacing of $5\lambda/4$ with each sheet fed directly but with a quadrature phase relationship. The objection to the latter is that additional supports are required for the reflector, whereas the close spacing permits the use of the same supports with crossarms or the use of spreaders. The simplest system is to use a neutral reflecting screen. Tuning is then confined to the one active sheet of radiators, and the spacing is diminished. If a reversible antenna is required, another sheet of radiators can be placed on the opposite side of the reflecting screen, all using one set of supports. If both radiating systems are tuned to the same frequency, a detuning stub is switched into the idle system.

49. Dipole Array Feeders. Feeders are always kept normal to radiators to maintain correct balance, and impedance matching of the feeder is done only at one point outside the antenna system, provided all internal conditions are correct. In multiple-feeder systems, each main feeder can be terminated before being joined to the main power trunk, which in turn is matched near this junction. Care must be observed to ensure that identical conductor lengths are included in both sides of the feeder when making bends, through switches, etc. If there is radiation coupling between radiators and feeder which sets up a parallel wave to ground, the nodal points in the feeder standing-wave pattern will be displaced mutually on the two sides of the feeder. To eliminate the parallel wave, one end of a $\lambda/2$ stub can be connected across the feeder

at some point and to a good ground at the other end, with a short circuit across the stub at $\lambda/4$ from the feeder junction. This stub is conveniently inserted vertically between the lower radiators and ground, as shown in Fig. 37*b*. The main feeder can then be terminated somewhere near the end with another stub or coupled section. On a very long feeder, the cumulative effect of line irregularities caused by insulators and bends may require another matching stub nearer the transmitter.

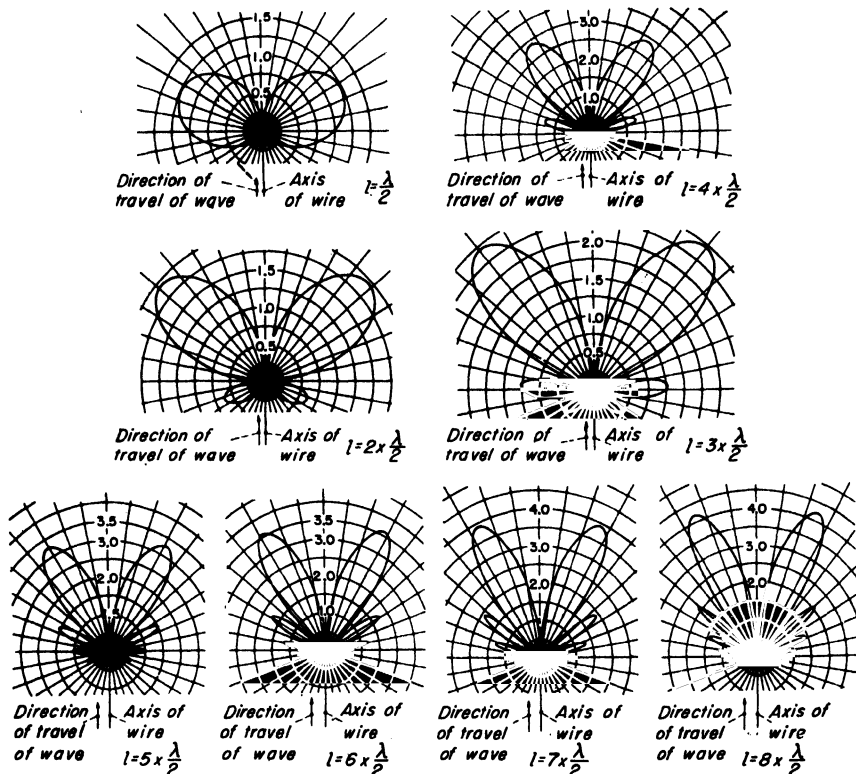
Dipole arrays of this type, made of single wires, will transmit band widths of the order of ± 2 per cent of optimum. To broaden this band slightly, all conductors in


FIG. 38. Field strengths due to straight wire carrying a traveling wave.

radiators and feeders must have low characteristic impedances, most conveniently accomplished by using double-wire hairpin radiators and four-wire feeders.

An array 2W4H (eight dipoles), with lowest radiators 1λ above ground, made of 0.100-in.-diam wire, and with 8-in. porcelain insulators with $3\frac{1}{2}$-in.-diam end fittings (insulator capacitance 1 $\mu\mu$f), has a wire length at resonance of about 0.45λ per dipole at 18 Mc. With 100-kw carrier input, the end potential on each dipole is 7,500 volts rms. A 3,000-ft 580-ohm two-wire balanced feeder used with this antenna had a transmission efficiency of 67 per cent.

Guyed supports for h-f antennas should be removed as far as possible from the radiator fields. It must be remembered that the radiation pattern customarily referred to is that at great distance, and that very near an array there are likely to be strong fields in any direction from the radiators. The use of breakup insulators in guys is determined by their natural period. Sometimes an insulated guy will resonate with the effect of insulator capacitance between sections when an uninsulated guy would be neutral. Few or no breakup insulators are preferred when guys can be

removed from strong fields and be of nonresonant lengths. The current flowing in any conductor is the induced potential over the impedance. In a strong field, the impedance of a guy wire or support must somehow be made as high as possible to suppress parasitic currents.

50. Traveling Waves on Long-wire Antennas. A long-wire antenna carrying a traveling wave without attenuation has the normalized radiation-pattern function

$$F(\theta) = \sin\theta \frac{\sin\left[\frac{\pi l}{\lambda_0}(c/v - \cos\theta)\right]}{\frac{\pi l}{\lambda_0}(c/v - \cos\theta)}$$

where θ = polar angle measured from the direction of the wire
c = free-space velocity
v = velocity of propagation on the wire
l/λ_0 = antenna length in free-space wavelengths

For most thin linear antennas $c/v = 1.0$; however, for other geometries c/v can be made greater than or less than unity. The first term in the above equation is the pattern function of an element of the wire, and the second term is the array factor for a continuous distribution in the form of $(\sin x)/x$.

Figure 38 shows a series of polar diagrams which are cross sections of the solids of revolution surrounding wires of different lengths. The intrinsic characteristic of diminishing amplitudes for successive lobes, following the main one closest to the direction of the wire, is a valuable property in directive applications. The four sides of a rhombic antenna are each radiators of this type, with the geometry arranged to add the main lobes and further suppress the minor lobes by wave interference. The fact of attenuation present in practice has but slight influence on the major lobe, and its principal effect is to fill in the nulls between lobes. A rigorous treatment of this type with attenuation and effects of ground has been published by Cafferata.[1]

51. Standing Waves on Long-wire Antennas. In the same manner, a long wire in free space m half waves long with the standing-wave distribution of current shown in Fig. 39 produces field distributions following these equations.[2]

For m odd,

$$F(\theta) = \frac{\cos\left(\frac{m\pi}{2}\cos\theta\right)}{\sin\theta}$$

Nulls occur at

$$\cos\theta = \frac{1}{m}, \frac{3}{m}, \ldots, \frac{m}{m}$$

Maximums occur at

$$\frac{m\pi}{2}\tan\theta\sin\theta = \cot\left(\frac{m\pi}{2}\cos\theta\right)$$

For m even,

$$F(\theta) = \frac{\sin\left(\frac{m\pi}{2}\cos\theta\right)}{\sin\theta}$$

Nulls occur at

$$\cos\theta = 0, \frac{2}{m}, \frac{4}{m}, \ldots, \frac{m}{m}$$

Maximums occur at

$$\frac{m\pi}{2}\tan\theta\sin\theta = \tan\left(\frac{m\pi}{2}\cos\theta\right)$$

These also neglect attenuation. The same general phenomenon as noted in the previous paragraph is present, except for the symmetry of the pattern. Figure 39 exhibits

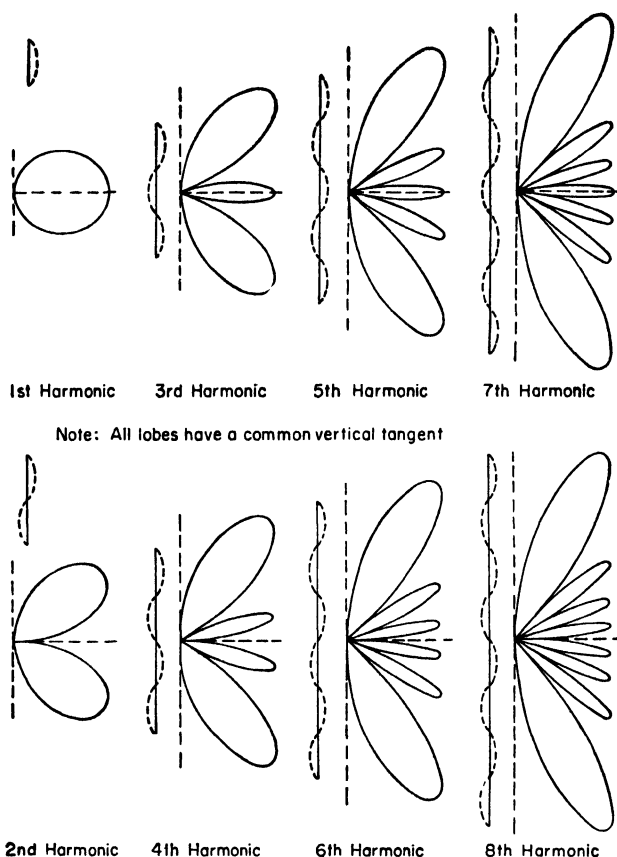
[1] See reference 195.
[2] See references 16 and 197.


FIG. 39. Polar diagrams of relative field-strength distribution for straight-wire antennas in free space with standing waves of current as shown, corresponding to the operation at various harmonics of the fundamental frequency of the antenna.

a series of patterns for medium lengths, and Fig. 40 compares directly a $7\frac{3}{4}\lambda$ and an 8λ pattern. This current distribution can be obtained only if the antenna is either "end-fed" or energized at a current maximum (shown in Fig. 39) by a balanced two-wire transmission line.

The free-space radiation-pattern function of a center-fed linear antenna of length l with a sinusoidal current distribution is

$$F(\theta) = \frac{\cos\left(\dfrac{\pi l}{\lambda_0}\cos\theta\right) - \cos\dfrac{\pi l}{\lambda_0}}{\sin\theta}$$

where θ is measured from the axis of the antenna.

The current distribution in this type of antenna is essentially sinusoidal if the antenna is thin (diameter less than $\lambda/100$).[1]

52. Horizontal Rhombic Antennas.[2] This basic type of antenna has won a permanent place in the h-f field. It is a traveling-wave system suitable for transmission and

[1] See references 9 and 11.
[2] References 192, 193, 194, 195, 197, 201, 214, and 222.

reception. It has singular merit for its broad frequency response. It is relatively inexpensive to construct and maintain and requires no tuning. Its main disadvantage is that it requires a large plot of land. A minor disadvantage is that its horizontal and vertical patterns are dependent one on the other, which sometimes imposes limitations on its effectiveness. The sharper the horizontal beam, the lower the angle of the vertical beam, and it is impossible to obtain high-angle radiation except at very low gain and very broad horizontal pattern. Another disadvantage is the need to dissipate a considerable proportion of the total input power uselessly in the terminating resistance to obtain aperiodicity and unidirectionality. Except for the very high cost of r-f energy per kilowatthour, this is not generally regarded as a serious deficiency in view of its other merits and in relation to the fact that the propagation medium varies normally so much in proportion as to obscure this loss.

Envelope parallel to wire

Radiation pattern $7\frac{3}{4}\lambda$ wire (sinusoidal current distribution)

Radiation pattern 8λ wire (sinusoidal current distribution)

FIG. 40. Comparison of radiation patterns for standing-wave current distribution of $7\frac{3}{4}\lambda$ and 8λ wires.

In transmitting, the potentials in the system are lower than for resonant systems. For the usual three-wire antenna with characteristic impedance of approximately 600 ohms, the maximum potential (at the input end) is approximately 7,750 volts rms for 100 kw carrier input. This is a desirable characteristic for high-altitude applications.

Rhombic horizontal antenna patterns are complicated by the skew geometry of the array and by the attenuated traveling waves. The main beam, usually the center of design interest, can be handled with adequate exactness by neglecting the attenuations, the complex dielectric properties of the ground, and the vertically polarized components of radiation. With these simplifications, the following equation[1] supplies the three-dimensional pattern:

$$F_{\theta,\Delta} = \left[\frac{\cos(\phi - \theta)}{1 - \cos\Delta\sin(\phi - \theta)} + \frac{\cos(\phi + \theta)}{1 - \cos\Delta\sin(\phi + \theta)}\right] \times \sin\left\{\frac{\pi l}{\lambda}[1 - \cos\Delta\sin(\phi + \theta)]\right\}\sin\left\{\frac{\pi l}{\lambda}[1 - \cos\Delta\sin(\phi - \theta)]\right\} \times \sin\left\{\frac{2\pi H}{\lambda}\sin\Delta\right\}$$

[1] See reference 17.

where ϕ = one-half side angle of rhombus
θ = azimuth angle with respect to major axis of rhombus
Δ = elevation angle with respect to horizon
l = length of one side of rhombus
H = height of wires above ground

The axial vertical pattern is obtained by placing $\theta = 0$. The horizontal plan pattern through the maximum in the axial vertical pattern is found after substitution of Δ max in this equation and solving for variable θ.

The main beam is horizontally polarized and is directed along the major axis of the array away from the feeder end. Long arrays have a multitude of smaller beams in all directions in vertical and horizontal angles. Owing to the attenuation of the traveling waves, there are no nulls in the patterns for the individual sides of the rhombus except in the axis of the wire, which is blanked by the pattern for the other three sides. There is no vertical or horizontal angle at which there is zero radiation, even though relatively very small in magnitude.

The antenna may be regarded as a transmission line which diverges from the feeder until it reaches an electrically large separation, then reconverges to the forward end virtually to a point. As the wires diverge, energy escapes from the system because there is no canceling effect from the opposite sides such as occurs in a close-spaced balanced transmission line. This divergence, however, is accompanied by a change in characteristic impedance unless means are taken to equalize it in relation to itself and to ground. An irregularity is introduced at the side corner so that the degree of suppression of standing waves on the terminal side is usually different from that on the feeder side. When its characteristic impedance is equalized by a spreading of three wires on each side, a more uniform match occurs throughout the system. In the case of receiving, this uniformity contributes to suppression of noise pickup from the rear. It is reported from comparative observations that a multiwire rhombic antenna is appreciably less susceptible to precipitation static interference than a single-wire system.

The three fundamental variables that control the radiation pattern are the electrical length of one side, the electrical height above ground, and the side angle at the bend. In all references, one-half of this side angle ϕ is employed as a parameter. We retain the established nomenclature for rhombic antennas herewith and assign ϕ to the half-side angle, θ to the azimuth angle with respect to the forward axis of the array, and Δ to the elevation angle. By various combinations of these factors, the main beam is directed in elevation and the beam width controlled in azimuth. At the same time the minor lobes are suppressed or enlarged in various directions so that the gain of the main beam can be slightly optimized by fine adjustment of all three parameters. Data based on an optimized design are presented in Fig. 41.

53. Rhombic Usage. The frequency range over which a rhombus can be used depends upon more than the mere fact of maintaining an impedance match which is satisfactory. Frequencies must be changed to accommodate changes in the propagation medium, and the function of a proper antenna application is to direct the radiant energy where it will be most effective. The desired radiation characteristics for various h-f circuits for various distances, times of day, seasons, and years must be determined for individual applications. Whether or not the use of a single rhombus fits the conditions encountered for the operating frequencies to be used must be investigated in relation to propagation requirements. Multipath transmission due to multiple hops and from varying heights of the different ionosphere layers imposes one of the most serious limitations on transmission speed and fidelity, and the vertical directivity of the transmitting and receiving antennas has much to do with multipath discrimination. Careful engineering of a propagation circuit may require different antennas for different frequencies regardless of the ability of a single antenna to accommodate a wide range of frequencies from an impedance-match standpoint.

In ordinary applications it has been customary to employ one rhombus for all frequencies in one direction, letting the pattern change as it will and accepting random effects in propagation. Where cost is more important than performance, this is the
FIG. 41. Rhombic-antenna design data.

best that can be done. In cases where optimum use is made of the propagation medium and where performance is the primary objective, it is often best to use a different antenna specially designed for each frequency for each point-to-point circuit. When this is done, the transmitting antenna need not be aperiodic, and the energy normally thrown away in a dissipative termination can be utilized by conducting it back to the input end via transmission lines which have the correct characteristic impedance, and phased and transformed to reenter the system in parallel with that from the transmitter. This reentrant feed method then improves the efficiency of the system for the operating frequency for which it is designed.

54. Receiving Rhombic Antennas. For receiving, either for single- or multifrequency operation, the antenna is resistance-terminated with a value as close as possible to its average characteristic impedance. Heavy-duty noninductive resistors are used, since small ones are frequently destroyed by induction from lighting. A static drain circuit to ground from the neutral of the termination is desirable to prevent the accumulation of static charges during precipitation. For transmission, where the dissipation is appreciable, high-loss transmission lines are used for terminating the antenna. Lines made of iron or stainless steel are commonly used and are assembled on low supports underneath the antenna, back and forth, to the required length. The
FIG. 42. Horizontal rhombic antenna.

length should be that which will provide at least 20 db attenuation at the lowest working frequency. Such a length is sufficient so that the reaction on the antenna is negligible whether open- or short-circuited. The latter is preferred because it can be directly grounded, thus serving as a static drain circuit also. The characteristic impedance is computed from formulas used for balanced two-wire lines.

The attenuation per unit length is given by the formula

$$\alpha = \frac{54.8 \times 10^{-6} (\sqrt{\rho\mu f}/d)}{Z_0} \quad \text{db/m}$$

where ρ = resistivity, microhm-cm
μ = magnetic permeability
f = frequency, Mc
d = wire diameter, cm
Z_0 = characteristic impedance, ohms

For the line to appear as a virtually pure resistance (phase angle of impedance less than 7 deg) the $\omega L/R$ per unit length at the lowest frequency must be less than 0.1. The inductance per loop meter is

$$L = \frac{Z_0}{3} \times 10^{-8} \quad \text{henrys/m}$$

A typical layout of a three-wire rhombic antenna with dissipation and feeder lines is shown in Fig. 42.

A rhombic antenna is a balanced system, and care must be taken to preserve good balance to ground. If a number of systems are located in the same plot, sufficient spacing must be allowed to maintain low mutual impedances between the nearest sides of adjacent antennas. When two rhombics are used in broadside as a single system, one common support can be used without balance problems, when fed symmetrically. When used with concentric transmission lines, care must also be taken to make a correct balanced-to-single-end transformation.

Fig. 43. Double-fishbone antenna.

55. Fishbone Receiving Antennas.[1] The fishbone antenna (Fig. 43) is an evolution of the wave antenna, adapted to the reception of horizontally polarized waves in the h-f band. Three different designs are used to cover the range 3 to 20 Mc, the differences being in the lengths of the dipoles. Fishbones are used singly, or with two in broadside. A typical system is 312 ft long. A single-bay system requires 10 poles and a two-bay system 16. The essential information on this type of antenna for construction purposes is tabulated below:

Length, doublets, ft	Optimum freq., Mc	Useful range, Mc	Width, 2 bays, ft	Length, total, ft	Best pole height, ft	Useful azimuth angle, deg
34	18	13-22	120	312	60	10
48	14	10-19	148	312	90	10
66	9	3-13	200	312	120	14

The schematic arrangement of the fishbone antenna is shown in Fig. 43. A central transmission line runs horizontally in the direction of the incoming signals. At equal intervals along this line, horizontal doublets are attached which are short enough to be nonresonant within the frequency range of the system, and near enough together to provide a uniform loading of the center line. Each pair of doublets loads the line with parallel capacitance and resistance. To keep the propagation velocity of the line above 90 per cent of free space, each doublet has a series capacitance near the point of attachment. The characteristic impedance of the main feeder is approximately 400 ohms. Two bays in parallel give an impedance of approximately 200 ohms, which can be matched directly into a balanced four-wire line to the receiving station. The end of the feeder toward the transmitting station is terminated in a noninductive resistance equal to the characteristic impedance of the feeder. This makes the system unidirectionally responsive by absorbing energy received from the rear. The fishbone antenna is a high-gain, broad-band, moderate-cost antenna with minimum land requirements. Even though the design is several years old, it remains one of the best receiving antennas for h-f point-to-point communication services.

56. Harmonic Wire Antennas of V Form.[2] Radiating systems using long wires having essentially sine current distributions have been called *harmonic wire antennas*. Several forms have been evolved, of which the two shown are typical (see Figs. 44 and 45). They have moderately high gain and relatively low cost. The main beam,

[1] See reference 189.
[2] See reference 197.

along the axis of the V, is horizontally polarized. The vertical pattern can be controlled to a certain extent by the height of the system above ground, but this is also related to the horizontal pattern in that the sharper the horizontal pattern, the lower the angle of the vertical pattern.

Figure 40 shows the comparison of the field-intensity patterns surrounding harmonic wires having lengths of $7\frac{3}{4}\lambda$ and 8λ. The main lobe nearest the wire axis contains most of the total radiated power. V antennas are arranged to utilize this main lobe from all wires of the system so that they add along the array axis and cancel as much as possible in all other directions. In Fig. 44 the two wires forming each side of each V are cophased, and the two sides of each V are antiphased. The rear V is fed 90 deg in advance of the forward V with equal currents to provide best reflecting action.
FIG. 44. V antenna with reflector.
FIG. 45. Unidirectional V antenna.

Figure 45 shows the simplest type of V antenna having unidirectional pattern. The lower wire in each side is longer than the upper by an amount equal to $\lambda/4$ in its projection upon the axis of the V and is excited parasitically from the upper wires, which are energized from the main feeder. Excited in this manner, the two wires on one side are approximately the equivalent of a single wire with a traveling-wave current distribution, producing a unidirectional pattern.

57. Antenna Systems for Ionospheric Forward-scatter Propagation. "Beyond-the-horizon" point-to-point communication is possible at frequencies above the maximum usable frequency (MUF) using a propagation phenomenon called ionospheric forward-scatter propagation. An ionospheric forward-scatter communication system consists of a high-power transmitter supplying a highly directive transmitting antenna oriented to direct its radiated energy toward the ionosphere at a low elevation angle in the direction of the great-circle path to the receiver location, and a highly directive receiving antenna oriented in the direction of the transmitter to receive the energy scattered from the ionosphere.

Scattering is caused by a turbulent region in the lower part of the ionosphere 40 to 200 miles above the earth with the scattering source (the volume illuminated by the transmitting antenna) generally located midway in the path. Since the source is in a turbulent state, the scattering is generally diffuse in nature, complicated by meteoric ionization and other phenomena. The scattering mechanism has a profound influence on the characteristics of the antenna system.

Only a few considerations pertinent to antenna design can be listed here. For details the reader is referred to the literature on the subject.[1]

The most useful range of path lengths for this type of propagation is from about 1,000 to 2,000 km.[2] Received signal intensity decreases rapidly with decreasing distance below about 1,000 km. The frequency range of greatest usefulness is from 25 to 60 Mc. Frequencies below about 25 Mc are subject to interference due to sporadic ionospheric propagation. In general, the lower frequencies in this range have been found to be best.

As stated above, high transmitter powers must be used because of the scattering mechanism. For simple communication systems, 5 kw of transmitter power is usually adequate at frequencies near 35 Mc using rhombic antennas. If the receiver used has a sufficiently low noise figure (an NF of 2 is adequate), external noise will be the limiting factor in this frequency band.

Multipath propagation from strong off-path reflections due to meteoric ionization, when it occurs, is a factor which reduces the propagation-path band width. The antenna side lobes should be sufficiently low to provide adequate suppression of off-path signals. Antenna beam widths should be narrow in azimuth for the same reason; however, there are other beam-width considerations stated later. Propagation-path band width will be limited by either antenna beam width or the natural beam width associated with the scattering process. Band widths of 50 kc can usually be obtained.

The following is a table of desirable antenna characteristics.

Desirable Antenna Characteristics*

Characteristic	Value
Horizontal beam width	8 deg or less
Vertical beam width including ground effects	6 deg or less
Maximum side-lobe level	40 db below main beam
Radiation efficiency	90% or greater
Horizontal orientation of beam	Normally on great-circle bearing between transmitter and receiver
Vertical orientation of beam	85 km above mid-point of great-circle path
Provision for reducing directivity or for varying direction of beam	For use during periods when scattering is not homogeneous and during periods when scattering meteoric components will provide higher signal-to-noise ratio
Band width over which characteristics are to be maintained	200 kc

* See reference 186.

The use of spaced-antenna receiving diversity is desirable. The diversity antennas should be placed in a line normal to the path with not less than 10 wavelengths spacing.

In general, horizontal polarization is preferred because the scattering losses are somewhat less than for vertical polarization. In addition, the reflection characteristics of the ground are more desirable, and, too, it helps to discriminate against man-made noise.

The *realized gain* of a directive antenna (defined as the ratio of signal intensity observed when the antenna is used to that observed when a reference or comparison antenna is used during the same period of time) is a function of the directivity of the antenna used at the opposite terminal and is influenced by diurnal variations in the propagating mechanism. Realized gains both greater than and less than *plain-wave gains* have been experienced. Refraction in the troposphere also affects realized gains, especially at low angles of radiation.

[1] October, 1955, *Proc. IRE* is devoted to ionospheric and tropospheric forward-scatter propagation. See reference 241.

[2] See reference 186.

In siting the antenna for low-angle radiation, the region in which ground reflections occur, which may be quite long for very low angles, should be flat to within a quarter of the antenna height if the 6-db increased gain is to be realized due to ground reflections.

To date, long rhombics 25 to 50 wavelengths on a side, arrays of smaller rhombics, large corner-reflector antennas, broadside arrays of corner reflectors, broadside arrays of dipoles, and arrays of Yagi antennas have been used in this service.

V-H-F ANTENNAS (30 TO 300 MC) AND U-H-F ANTENNAS (300 TO 3,000 MC)

Developments in communications, f-m and television broadcasting, radar, navigational aids, and many other applications have given birth to an endless variety of antennas during recent years. This treatise cannot possibly include reference to all of them though certain basic types must be included. From these, other types can be understood. The mechanical design of antennas in these bands departs radically from those for lower frequencies because supported wires usually are replaced by rigid members, many insulators are eliminated, metallic line sections are used as insulators and in other ways. Some antennas must respond uniformly to very large band widths; some must have very high directivity; others must have switchable patterns, rotating or waving patterns, and other special properties. Since such antennas are often located in high places subject to severe weather, designs must be extremely robust. Most forms are prefabricated before erection. Electrically some are very complicated, with ingenious forms of radiators and feeding systems. Some use sheet distributions of currents instead of linear distributions, magnetic instead of electric dipoles, and many use flat, angular, or parabolic reflecting screens. In the higher-frequency portion of the u-h-f band, wave-guide feeders are frequently used instead of ordinary transmission lines. All the antenna technology found in all the lower frequencies is employed in these bands together with many other principles peculiar to these bands.

58. Electric Dipoles. A description follows of certain basic radiator types used alone or in antenna arrays (see Fig. 46).

Straight Electric Dipole (Fig. 46*A*). A straight rod or tube of length approximately $\lambda/2$, mounted with a metallic rod attached at the mid-point (zero potential) and normal to it. To increase its band width, its diameter is made relatively great, or it may be ellipsoidal instead of cylindrical in extreme cases.[1] It can be shunt-fed with a balanced transmission line.

Figure 46*B* is a center-fed dipole supported by a $\lambda/4$ transformer. One side of this support acts as a continuation of the concentric feeder and, where the inner conductor emerges at the center of the radiator, it is connected to the other side. This arrangement uses the $\lambda/4$ supporting insulator also as a single-end-to-push-pull transformer to provide the required balanced feed potential at the center of the radiator.

Figure 46*C* is a form where both sides of the $\lambda/4$ support insulator act also as concentric feeders. In this case, charges flow out from the inside of the outer conductors of the feeders and propagate along the outsides of the transformer and radiator where they set up standing waves in the usual way. The inner conductors for the two feeders are connected together.

Figure 46*D* shows a method of dipole construction by which the impedance at the center point of feed can be made resistive in any ordinary amount required for correct balanced feeder matching.[2] The $\lambda/4$ supporting transformer can be shunt-fed from a balanced line, as at points *B*, or the radiator can be excited directly when the feeder is attached at points *A*. The charges that flow on the outside of the tubular conductors set up the usual standing wave of current. The length is made somewhat less than $\lambda/4$ each way from center so that, at the feed point, the impedance appears as a resistance in series with a capacitive reactance. Currents propagated inside the tubes, by virtue of the concentric conductor in the inside acting as a transmission line

[1] See reference 294.
[2] See reference 259.

(and also as a mechanical support for the two halves of the radiator), are reflected from short-circuiting disks, which make the inner lines appear as inductive reactances. When these are adjusted so that this reactance forms a parallel-resonant combination with the external impedance of the radiator itself, the feed impedance is made resistive. By proportioning the external length and the internal short-circuit position, the feed-point resistance can be adjusted over a wide range to a desired value.

Figure 46*E* uses somewhat the same principle as the previous form, except that the inductive tuning to correct the power factor of the radiator portion is obtained by placing a short circuit across the $\lambda/4$ support transformer at the correct position. It can be fed with a balanced feeder at points *A* or *B*.

These five forms are excellent examples of multiple utilization of all parts of the system for electrical and mechanical purposes. Those using the $\lambda/4$ transformers for supports are ordinarily attached to reflecting sheets or to some structural members for an array of such radiators. They lend themselves to virtually all-metal welded construction with a minimum of insulation.

Figure 46*F* is a form frequently used to obtain a vertical radiator which terminates a concentric feeder.[1] The outer conductor is, in principle, turned back $\lambda/4$ while the center conductor continues outward for $\lambda/4$. This gives a vertical dipole in which the image charges from the inside of the sheath balance those flowing upward in the projection of the inner conductor. The skirt forming the lower half of the dipole is insulated from the sheath of the feeder and suppresses sheath currents on the feeder below it. In practice, however, there is considerable coupling to the feeder from the skirt, and it should be taken into account in the design. Since the feed-point impedance of such a radiator is very nearly that common to many types of coaxial line, a satisfactory impedance match and single-end-to-balanced transformation are achieved simultaneously.

Figure 46*G* is a radiator less than $\lambda/4$ long that projects from a short coaxial stub section which is short-circuited near its lower end.[2] The antenna presents an impedance of resistance and capacitive reactance which is tuned to a resistive condition at the feed point at the upper end of this stub, acting as a tuning inductance. Two or four horizontal $\lambda/4$ rods project outward from the lip of the concentric stub, which is attached to a mast. The impedance at the lip is adjusted by radiator length and stub length to be correct to match a concentric feeder attached to the mast. The radial rods carry the image charges for the radiator portion and by virtue of their $\lambda/4$ length bring a potential node at the transmission-line sheath. This suppresses currents on the sheath below. In this way a perfect impedance match can be made, and the assembly is compact and rugged. A folded-monopole antenna can be fed in a similar manner.

The forms in Fig. 46*H* and *J* do the same thing in slightly different ways. In the former, the suppressor section, in the form of a cylindrical skirt connected to the outer sheath only at its lower end and being $\lambda/4$ long, presents a very high impedance at its upper edge. Thus the flow of charges from the inside of the sheath as they emerge from the feeder is reflected from this upper edge as from an open circuit. The standing waves set up on the outside of the sheath over it are images of the charges flowing in the projection of the inner conductor, which is also $\lambda/4$ long. In the *J* form, the same thing takes place except that the stopper section is simply a parallel conductor forming a $\lambda/4$ transformer with the lower part of the projected center conductor which transforms the end-feed impedance back to the coaxial feeder with a value equal to that at the middle of the $\lambda/2$ radiating portion. These three forms of coaxial antennas are specially adapted to vertical antennas which must be mounted at the top of a high flagpole type of support. In practice, the current on the feeder is not completely suppressed, and this point should be considered in the design.

Figure 46*I*, composed of two straight dipoles in space quadrature and excited in phase quadrature, is known as the *turnstile*.[3] When adjusted for equal power and

[3] See reference 257.
FIG. 46. Basic dipole antennas.
FIG. 46. Basic dipole antennas. (*Continued.*)

exactly 90-deg phase difference between the two quadrature dipoles, the radiation pattern is virtually circular in the plane of the dipoles. As a single element, considerable energy is radiated in the direction normal to the plane of the radiators, and for the specified excitation, the field in this direction is circularly polarized. The polarization can be changed by adjusting either the power divisions or the relative phasing or both. In this case, the radiation pattern in the plane of the turnstile is elliptically shaped. When two or more such radiators are stacked at $\lambda/2$ intervals and successively cophased, maximum radiation occurs in the plane of the radiators. When successive layers are antiphased, directivity normal to the planes of the turnstiles is obtained.[1]

A turnstile element has a certain advantage in providing a greater band width than that of the individual dipoles. This comes about from the method of feeding and phase-shifting whereby the feeder to each radiator is terminated and the two sections excited from a common generator by means of parallel lines from a junction point with the main feeder, one branch being $\lambda/4$ longer than the other.[2] This extra $\lambda/4$ section of line, in addition to providing the 90-deg phase lag, acts as an impedance-inverting section. Both radiators change impedance equally as the frequency is changed from mid-band, but the impedance inversion in one feeder causes a compensating effect at the main junction with the other feeder. This is a valuable property per se.

Figure 46*K* represents the *biconical antenna* whose principal special property is intrinsically greater band-width response than ordinary radiators have.[3]

Figure 46*L* presents again the folded dipole. As an impedance transformer and for its greater cross section providing broader band response than a simple straight dipole, it has special value in certain v-h-f and u-h-f applications.

Figure 46*M* is a variation in principle of Fig. 46*B*, where the central supporting member is a tube forming the outer conductor of a coaxial transmission line. The tube is slotted to a depth of $\lambda/4$, and the inner conductor of the transmission line attaches to one side of the $\lambda/2$ dipole welded to the tube. In general, this type of slotted-coaxial section is both a balance-to-unbalance transformer and an impedance transformer in the ratio of 4:1. That is, the impedance at the balanced terminals (the open end of the slotted section) is four times the impedance of the unbalanced line (assuming it is terminated in a matched load) in shunt with the reactance of the balanced stub formed by the slot in the coaxial line. If the slot is effectively $\lambda/4$ long, its impedance is infinite and the impedance transformation is 4:1. In practice, the characteristic impedance of the coaxial line is modified slightly by the presence of the slot. Unless the diameter of the coaxial line and the slot width are very much less than the wavelength, considerable radiation will occur from the slot.

Figure 46*O* is an example of a dipole, capable of many variations, where linear conductors are replaced by plane sheets of selected shapes for obtaining special characteristics.

In all these forms of electric dipoles, band width can be increased by increasing the radiator cross section when the application is associated with wide-band systems. Their radiation patterns are individually quite similar to any simple straight dipole, except for the turnstile element.

59. Magnetic Dipoles. Certain applications, such as navigational aids, require for their success the radiation of a field which is virtually pure horizontal polarization at any orientation from the antenna. Other less critical applications also use horizontal polarization, the purity of which is not essential. To obtain virtually pure horizontal polarization a vertical magnetic dipole can be used. There are several types in existence, and others appear from time to time. What is wanted in a magnetic dipole is a loop of fairly large electrical diameter to have a high radiation resistance, with a uniformly distributed current around it, all elements of which are in time phase. It has generally been necessary to approach this by configurations made up of bent electric dipoles having standing-wave current distributions. The various forms developed

[1] See reference 291.
[2] A bridge-type network for this purpose is given in reference 295.
[3] See references 16, 265, and 88.

exhibit ingenuity in making magnetic dipoles from electric dipoles, with varying degrees of compromise.

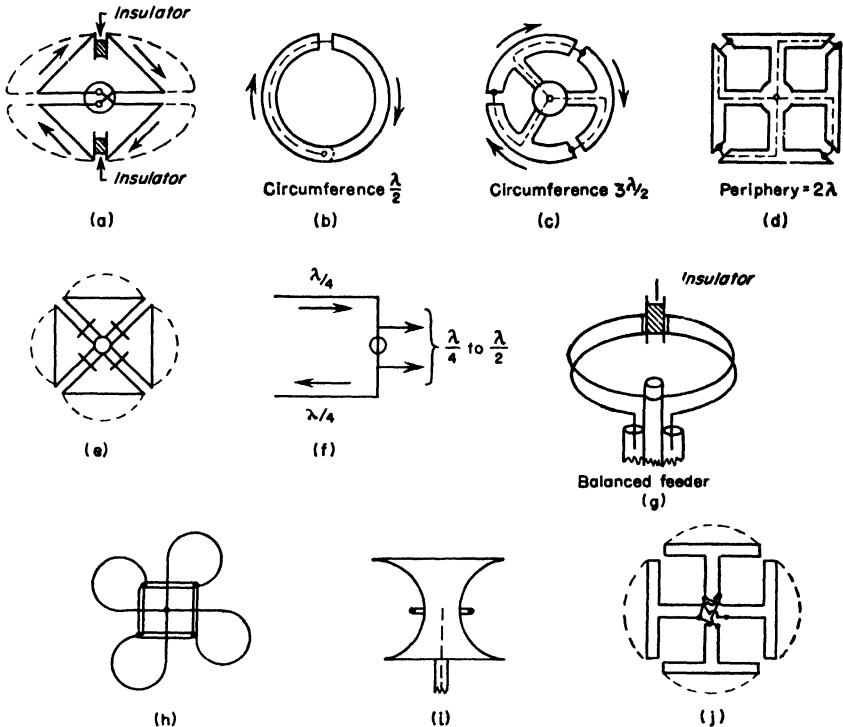
Some of the most practical forms are shown in Fig. 47. In this figure, *a* is a square loop made up of two electric dipoles, folded at their centers and near their ends.[1] When they are attached by means of insulators at the ends, the current at the corner is not zero, though it is much less in amplitude than at the other corners, where the two dipoles are center-fed in balanced antiphased relationship. It is fed by a balanced


FIG. 47. Magnetic-dipole antennas of various forms.

feeder at the center. This has been used in aviation navigational aids. It is characterized by a nonuniform current distribution which produces an oval pattern, and by relatively low radiation resistance because of its small electrical diameter (approximately $3\lambda/16$ per side). The dipoles are made of wide bars of metal, and the feeder lines are ordinarily shielded up to the two corners where they are energized.

Figures 47*b*, *c*, and *d* are three versions of magnetic dipoles.[2] A circular or polygon loop, sectionalized and fed as shown from a coaxial feeder, permits cophasing the currents in the successive elements for relatively large electrical diameters and provides high values of radiation resistance to be realized. As the loop is increased in diameter, the periphery is sectioned into a larger number of segments, each $\lambda/2$ long, with its own radial feeder. One-half of each radiator acts as the coaxial line for the succeeding radiator.

Figure 47*e* is a square (or alternately a circular) loop radiator $\lambda/2$ per side. The ends are not closed and are connected by radial supporting stubs which are short-

[1] See reference 243.
[2] See reference 285.

circuited $\lambda/4$ from each corner.[1] Thus the current in each side is cophased, while the balanced radial stubs suppress radiation from the antiphased portions of the standing-wave system. This loop can be shunt-excited by a balanced line across one of the radial stubs, or at two such symmetrically opposite points in parallel. The pattern in the plane of the loop is squarish, the maximum field being opposite a side, and is about 1.29 times that opposite a corner.

Figure 47*f* is called the *U antenna*. A special characteristic of this radiator is that it approximates a spherical radiation source, quite unlike all other types of electric and magnetic dipoles shown.

Figure 47*g* is a folded $\lambda/2$ dipole bent in the form of a loop, using balanced feed.[2]
FIG. 48. Slot antennas fed by coaxial transmission lines.

Figure 47*h* is the *cloverleaf* radiator. In this case the tower itself (square) serves as the outer conductors of a concentric line, through the center of which runs the main feeder. Each cloverleaf consists of four loops of rigid tubing, each loop starting at the feeder and terminating on one corner of the tower and bent to include a straight portion and a three-quarters circle. The length of each loop of the cloverleaf is about $\lambda/2$.

Figure 47*i* is a loop radiator located at the focus of a reflector which is a parabola of revolution. The reflector, depending upon its aperture, flattens the radiation pattern. The exciting loop is energized by a coaxial feeder running along the axis of the assembly.

Magnetic dipoles are used as elements in antenna arrays disposed in vertical or horizontal arrangements depending upon the application.

60. Slot Antennas—Current-sheet Radiators. A thin slot cut into a metallic surface with its long dimension approximately $\lambda/2$ is a simple yet efficient radiator by

[1] See reference 321.
[2] See reference 309.

virtue of the currents flowing over the metallic surface.[1] This general type of antenna is called a slot antenna, or current-sheet radiator. It can be energized from a parallel-wire line or from a coaxial line, as shown in Fig. 48. A large mismatch will exist if the latter is used because for $L \doteq \lambda/2$, the input impedance at a pair of terminals at the slot center is approximately 500 ohms (a better match can be achieved by feeding off center).

The general problem of determining the radiation from a slot in a metallic surface can be formulated with the aid of the equivalence theorem.[2] That is, the radiated field may be determined from a distribution of magnetic currents M and electric currents J flowing on a closed surface surrounding the metallic ground plane and radiating as if they were in free space (*i.e.*, in the absence of the ground plane). The current densities are related to the tangential components of E and H on the ground plane, including the slot, by

$$\vec{M} = \vec{E} \times \vec{n}$$
$$\vec{J} = \vec{n} \times \vec{H}$$

where $\vec{E}$ = vector representation of the tangential electric field

$\vec{H}$ = vector representation of the tangential magnetic field

$\vec{n}$ = unit vector normal to the ground plane

The radiation pattern of a slot in an infinite metallic ground plane is a doughnut-shaped pattern of revolution independent of ϕ, as shown in Fig. 49. The radiation is polarized in the ϕ direction. Since radiation occurs on both sides of the metallic surface the polarization changes direction (from the positive ϕ direction to the negative ϕ direction) as one passes through the metallic surface. If L is $\lambda/2$ the pattern shape is independent of ϕ and is given by

$$F(\theta) = \frac{\cos\left(\frac{\pi}{2}\cos\theta\right)}{\sin\theta}$$

In practice, the ground plane is finite and the radiation pattern is not independent of ϕ. The field produced by the currents on the finite metallic surface as well as the field radiated by the slot must be considered. The pattern is the superposition of these fields.

FIG. 49. Radiation pattern of vertical slot in infinite flat sheet.

By means of Babinet's principle, extended by Booker,[3] many of the problems of slot antennas can be reduced to situations involving complementary linear-dipole antennas for which solutions have already been obtained. A slot antenna and its complementary linear-dipole antenna are illustrated in Fig. 50. The complementary linear antenna consists of a perfectly conducting flat strip identical in size and shape to the slot antenna cut into an infinite perfectly conducting ground plane. The radiation characteristics of these

[1] See reference 9.
[2] See references 12 and 13.
[3] See reference 255.

antennas are similar. That is, the shapes of the radiation patterns of the two are identical, but the polarization is such that E and H are interchanged in the two cases. Also, as noted above, the component of E normal to the ground plane is discontinuous.

The input impedances of a slot antenna Z_s and its complementary linear-dipole antenna Z_d are related by

$$Z_s Z_d = \frac{Z_0^2}{4} = 35{,}476 \text{ ohms}$$

where Z_0 = intrinsic impedance of free space = 120π ohms.

If the slot antenna is enclosed with such a box that zero susceptance is shunted across the input terminals, the input impedance is doubled. This would be the equivalent of placing a "tuned" reflector element behind the complementary dipole.

FIG. 50. A slot antenna and its complementary linear (dipole) antenna.

Methods for exciting sheets of currents on large metallic surfaces, as distinguished from linear distributions, using slots or gaps are shown in Fig 51.

Figure 51*a* is a turnstile assembly of fishtail sheets in which is propagated a continuous distribution of in-phase currents flowing normal to the supporting mast. The figure shows the radiators in one plane only. This design is made of tubular members as a skeleton sheet to reduce wind surface; otherwise it functions as if made of continuous sheets. Its fishtail form was empirically developed to obtain optimum current
FIG. 51. Current sheet radiators.

distributions and impedance characteristics over a very broad frequency band. Each wing is attached to the mast at top and bottom. A coaxial line rises to the middle of the assembly along one feeder rod to which it is connected. The center conductor emerges at this point and is connected across to the middle of the feeder of the opposite wing. This provides the balanced feed required for the radiators in one plane. Two such planes of radiators in quadrature, excited 90 deg out of phase, comprise a turnstile having a nearly circular pattern normal to the antenna axis.

Figure 51*b* is a current sheet bent into a cylinder (a slotted-cylinder antenna) having a circumference of about $\lambda/2$.[1] The slot acts as a line which is excited with a standing wave by a balanced feeder or by a coaxial feeder arranged for single-end-to-balanced transformation (as in the case preceding). The cylinder can be from one-half (slot

[1] See references 242, 245, 277, 282, 305, 313, 314, 329, 330, and 280.

ends open) to one wavelength long (ends closed) in terms of the phase velocity of a system of this type. The potentials along the feed slot are all cophased, setting up parallel current flow around the circumference of the cylinder at all points. This type of antenna has moderate band width and is very simple to construct.

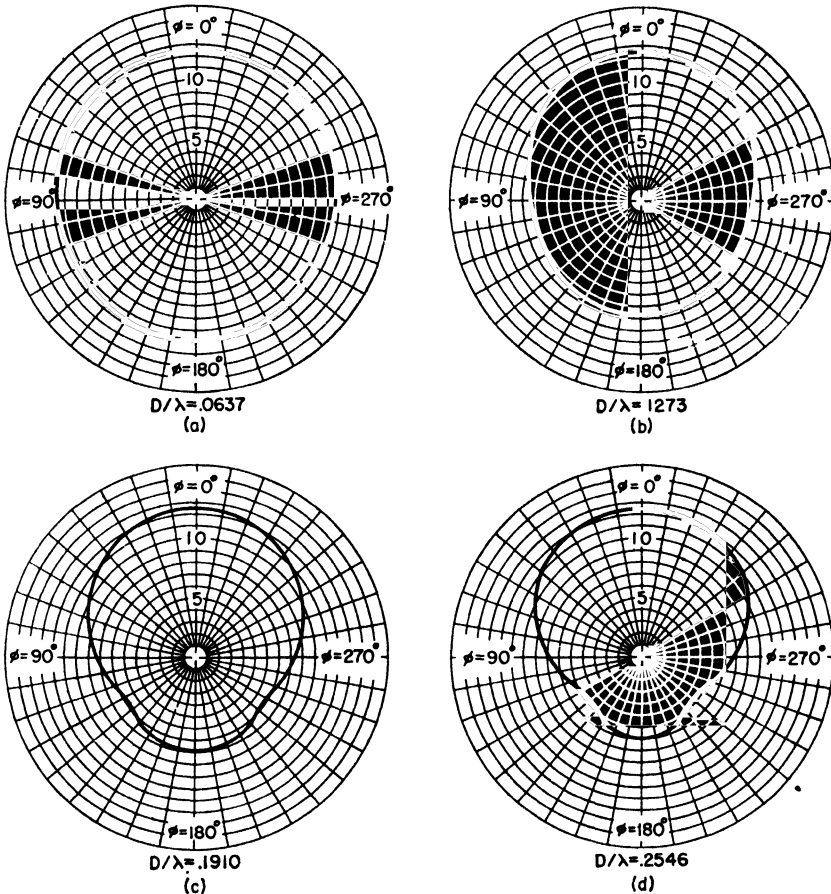
Figure 51c is a cylindrical (or alternately polygonal) current sheet radiator having three vertical slots. Its theory is similar to the preceding example except for the three


FIG. 52. Patterns for a single slot in a cylinder. The slot is located at $\phi = 0$ deg.

slots, the purpose of which is to obtain a pattern that is a circle. The three slots are fed in parallel at their centers by separate feeders.

Slotted-cylinder antennas have found considerable application for broadcasting a horizontally polarized wave with an omnidirectional pattern in the horizontal plane. They are similar to magnetic dipoles in this respect. Vertical directivity can be obtained by stacking. If the diameter of the cylinder is not too large, a single slot with its long dimension parallel to the axis of the cylinder produces a pattern which, for most purposes, is omnidirectional in the plane normal to the axis. In the orthogonal plane, the pattern is a figure eight. As the diameter increases, the antenna becomes directional. Therefore, the diameter is a simple parameter for pattern control.
FIG. 53. Patterns of slotted-cylinder antennas having diameters large in terms of the wavelength. Slot is located at $\phi = 0$ deg.

Another method of pattern control consists in arraying a number of slots around the periphery of the cylinder. A wide variety of patterns can be obtained by varying the excitation.

Calculated radiation patterns for a single slot in a cylinder for various cylinder diameters are shown in Figs. 52 and 53.[1] The corresponding variations in relative phase of the radiated field are shown in Fig. 54. Calculated amplitude and phase patterns for two slots diametrically opposite each other, fed equally, and in phase are shown in Figs. 55 and 56 for various cylinder diameters.

61. Elliptical Polarization. The state of elliptical polarization of a plane wave at a point in space may be described in terms of the relative amplitudes and phases of two perpendicular vector field components (electric or magnetic). For example, the ratio of the field components is a complex number whose amplitude is the ratio of the component amplitudes and whose phase is their relative phase difference, and is often used to describe a state of elliptical polarization.

A chart showing the polarization ellipses as a function of the ratio of two orthogonal components (E_2/E_1) and their relative phase difference δ is shown in Fig. 57.[2]

Techniques for handling and representing elliptically polarized waves are covered in a series of excellent articles in the literature.[3]

62. The Helical Antenna.[4] A helix may radiate in many modes. Two of these radiation modes are: (1) the axial-beam mode characteristic of the helical-beam antenna and (2) the normal mode in which the field is maximum in a direction normal to the helix axis.[5] For the latter case, the helix is small compared with a wavelength and is inherently a narrow-band element. In the axial mode the helical-beam antenna has inherent broad-band pattern, impedance, and polarization characteristics. There is a natural adjustment of the phase velocity as a function of frequency so that the fields from each turn add nearly in phase in the end-fire direction over nearly a 2 to 1 frequency range. The terminal impedance is relatively constant over the same frequency range because of the large attenuation of the wave reflected

[1] See reference 313.

[3] See references 255, 270, 275, 283, 307, and 315.
[4] See references 9 (Chap. 7), 262, and 278.
[5] See reference 324.
FIG. 54. Curves showing relative phase of the field with azimuth for a single slot in a cylinder. The slot is located at $\phi = 0$ deg in each case.

from the open end of the helix. The polarization is nearly circular over this same range.

Examples of helical-beam antennas are shown in Fig. 58. They are simple to construct. Figures 59 and 60 define the notation used in antenna design. They are

D = helix diameter (center to center)
C = helix circumference $= \pi D$
S = spacing between turns (center to center)
α = pitch angle $= \arctan (S/\pi D)$
L = length of one turn
n = number of turns
A = axial length $= nS$
d = conductor diameter

The dimensions for the helical-beam antenna (for broad-band end-fire operation) are

Pitch angle	$12° < \alpha < 15°$
Circumference	$\frac{3}{4} < C/\lambda_0 < \frac{4}{3}$
Turns	$n > 3$
Upper limit for diameter	$D_u = \dfrac{\sqrt{2S/\lambda_0 + 1}}{\pi}$
Conductor diameter	$0.006 \leqq d/\lambda_0 \leqq 0.05$
Ground-plane size	$>\lambda_0/2$ in diameter

The following antenna characteristics hold only for these dimensions.

The helical-beam antenna has a terminal impedance which is nearly pure resistance with a value between 100 and 200 ohms. To within about ± 20 per cent the terminal impedance of an antenna whose dimensions are within those listed above is given by the empirical relation

$$R = 140C/\lambda_0 \quad \text{ohms}$$

A method of feeding the antenna is shown in Fig. 61. Beyond point Q in this figure, the helix lies in the surface of an imaginary cylinder. Between P and Q, the helix conductor lies in a plane through the helix axis and at approximately the same pitch angle as for the helix proper.

D/λ=.0637 (a)

D/λ=.1273 (b)

D/λ=.1910 (c)

D/λ=.2546 (d)
FIG. 55. Patterns for arrays of two diametrically opposed slots, fed equally and in phase. Slots are located at ϕ_1 = 0 deg and ϕ_2 = 180 deg.
FIG. 56. Variations in relative phase of the fields of arrays of two slots.
FIG. 57. Polarization ellipses as a function of the ratio E_2/E_1 and phase angle δ (wave approaching).

The relative phase velocity along the helical conductor when the antenna is operating in the beam mode (see conditions above) is

$$\frac{c}{v} = \frac{S/\lambda_0 + [(2n+1)/2n]}{L/\lambda_0}$$

where v = phase velocity along the helical conductor

c = free-space velocity

This corresponds to the Hansen-Woodyard criterion for increased directivity.
FIG. 58. Arrangement for producing axial mode of radiation.
FIG. 59. Helix dimensions.

A good approximation to the far-field pattern can be obtained from an analysis which replaces the helical-beam antenna by an array of n isotropic point sources, each source replacing a single turn of the helix. The normalized pattern function is

$$F(\theta) = \sin\left(\frac{\pi}{2n}\right)\frac{\sin(n\psi/2)}{\sin(\psi/2)}$$

where $\psi = 2\pi[(S/\lambda_0)\cos\theta - (L/\lambda_0)c/v]$

θ = angle measured from helix axis

$\sin(\pi/2n)$ = normalizing factor for increased-directivity condition

Empirical relations for the beam width of a helical-beam antenna (see conditions above) are

$$\text{Half-power BW} \doteq \frac{52}{C/\lambda_0\sqrt{nS/\lambda_0}} \quad \text{deg}$$

$$\text{BW between first nulls} \doteq \frac{115}{C/\lambda_0\sqrt{nS/\lambda_0}} \quad \text{deg}$$

The directivity is given approximately by

$$D \doteq 15(C/\lambda_0)^2 n(S/\lambda_0)$$

The axial ratio (AR) for the helical-beam antenna for the condition of increased directivity is given approximately by

$$AR \doteq \frac{2n + 1}{2n}$$

If n is large, the axial ratio approaches unity and the polarization is nearly circular.
FIG. 60. Relations among cirumference, spacing, turn length, and pitch angle of a helix.
FIG. 61. Terminal arrangement of helical-beam antenna.

63. Antennas for Radiating Simultaneous Vertically and Horizontally Polarized Fields. In certain v-h-f communication applications for aviation, it is required to transmit from the ground station signals of both horizontal and vertical polarization. This can be accomplished in a number of ways with separate antennas energized from a common transmitter but it is preferable to employ a single radiating system.

Figure 62 shows a type of antenna which radiates an omnidirectional circularly polarized field, especially desired in v-h-f aviation communication because of its freedom from orientation effects of the receiving antenna whether the latter be an electric or a magnetic dipole. The four electric dipoles, with equal cophased currents, form a square loop, except that the dipoles are tilted at an angle of 30 deg from their common plane, like sections of a quadruple screw thread.[1]

FIG. 62. Polarization antenna for v.h.f.

64. V-h-f Vertical Arrays. V-h-f f-m and TV broadcasting employs horizontal polarization (in most cases) and requires omnidirectional coverage. To obtain the most effective concentration of radiated power toward the horizon, many forms of vertical arrays have already been evolved using magnetic dipoles, turnstile elements, or current sheets. By increasing the height of the stack, the gain can be adjusted, theoretically, to any desired value. The limitations are set by cost, feeder-line details, and the conditions encountered at the antenna location. The antenna system is

[1] See reference 260.

always located as high above surrounding terrain as possible, using a high tower, building, or natural height. In typical locations the antenna and feeder system is exposed to rigorous weather conditions, and the electrical and mechanical design must be adequate to endure them. In view of the great difficulty of making changes or adjustments after erection, such systems are now usually prefabricated and pretuned.

Gains (with respect to $\lambda/2$ dipole) for a vertical stack of magnetic dipoles fed with equal currents, cophased, and for two forms of turnstile arrays are tabulated below:

Vertical Stack of Magnetic Dipoles

Spacing, deg	Number of magnetic dipoles					
	2	4	6	8	10	12
	Vertical gain, db					
180	1.9	4.5	6.2	7.2	8.0	8.9
360 (optimum)	3.2	6.3	8.4	9.6	10.8	11.7

Vertical Stack of Turnstile Elements

	Number of layers				
	2	4	6	8	10
	Vertical gain, db				
Original turnstile	2.0	3.5	5.0	6.5	8.0
Improved turnstile (double coaxial feed)	1.25	2.75	4.25	5.75	7.2

Several commercial types of vertical arrays for f-m and television broadcasting are in existence, and others are appearing frequently, using various electric and magnetic dipoles as elements. There are arrays of cloverleafs, square loops, circular loops, circular folded dipoles, folded dipole turnstiles, etc.

Where horizontal loops (magnetic dipoles) are arrayed vertically along a common axis and all energized with equal in-phase currents, the normalized vertical pattern factor is

$$F(\theta) = \frac{\sin\theta \sin\left(\frac{n\beta_0 d}{2}\cos\theta\right)}{n \sin\left(\frac{\beta_0 d}{2}\cos\theta\right)}$$

where θ = angle measured from the axis of the array
n = number of loops in the array
$\beta_0 d$ = electrical spacing between loops
= $360\, d/\lambda_0$, deg

This equation does not include the effect of ground reflections, which are usually of minor interest at receiving points along the ground. The figure of merit for an array, including the gain characteristics, depends upon the vertical pattern for the array alone. However, there will be some variation of effective power radiated in azimuth in arrays using elements having noncircular patterns.

Arrays of electric dipoles may also be used, and when directive radiation is required,

they will generally employ elements of this type. Current sheet radiators, singly and in vertical arrays, are also used.

The choice of f-m antennas depends upon many factors, including electrical and mechanical stability, immunity to weather, gain, band width, and, finally, effective radiated power toward the horizon per dollar of installed cost, including tower and feeders.

Television antennas are subject in general to the same requirements as f-m broadcast antennas, with the additional very important one of wide band width, with consequent standing-wave ratio on the feeder of 1.1 or less over the entire video spectrum of the channel.

When a magnetic dipole is made of horizontal electric dipoles, it is interesting to note that a triangle of three electric dipoles produces more nearly circular pattern than any other number.[1]

65. Flat (Planar) Arrays. Radiation control can be effected by planar and by cubical arrays. The cubical array is unusual because it is complicated mechanically and electrically, and almost all desired patterns can be obtained with planar arrays, often with linear arrays. However, the use of reflecting surfaces, in the form of continuous metallic sheets or metallic screens, produces in effect a shallow cubical array because of the radiation from the images in the reflector.
FIG. 63. Colinear array of three pairs of dipoles.
FIG. 64. Linear array of parallel dipoles.

Flat arrays, also called *bedspring* or *billboard arrays*, have been developed in great variety for radar, most of which fall under the following types:

1. Colinear array of dipoles (Fig. 63)
2. Parallel linear array of dipoles (Fig. 64)
3. Two-dimensional (planar) array of dipoles (Fig. 65)

66. Lobe Switching. Lobe switching is a process of producing overlapping patterns alternately and using the equisignal overlap for direction finding (see Fig. 66*a*). To obtain this, the main pattern is a few degrees from the perpendicular to the plane of the array. The methods used to obtain a pattern of the desired shape which is slightly skewed from the perpendicular are notably the following:

1. Dividing the array into two sets of radiators: one producing a pattern which, in terms of azimuth or elevation angle, is an even function, and the other an odd function. By

[1] See reference 266.

inverting the polarity of the feed for the latter, the combined pattern is switched from one side to the other of the normal (Fig. 67).

2. By mechanically shifting the plane of an array periodically in one or two directions.

3. By using two separate arrays oriented to provide the desired overlap using constant excitation if fixed overlapping patterns are wanted and switching the excitation to the two arrays if lobe switching is wanted.
FIG. 65. Square planar array of 36 dipoles.

Arrays have been designed which produce even-function and odd-function patterns simultaneously.[1]

Most of the arrays for communication, navigational radio systems, and radar are composed of combinations of these various characteristics. In a treatise of this scope it is possible only to indicate briefly the principles for this vast field of design.

FIG. 66. Examples of lobe-switching and conical-scanning radiation patterns.

67. Pattern Shaping with Arrays. Pattern shaping is usually accomplished by controlling the relative amplitude and phase of the excitation of the elements of the array (see Sec. 29). If pattern multiplication is applicable, the distributions most commonly used are:

1. *Uniform currents in all radiators.*[2] This distribution produces maximum directivity and relatively high side lobes.

2. *Binomial current distribution symmetrically from center.*[3] This distribution results in zero side-lobe level with a decrease in directivity.

[1] See reference 323.
[2] See references 39 and 93.
[3] See reference 58.

3. *Dolph-Tchebyscheff current distribution (symmetrical).*[1] This distribution optimizes the relation between beam width and side-lobe level. That is, if one is specified the other is minimized.

4. *Fourier current distributions (symmetrical).*[2]

5. *Empirical distributions.*

These distributions are for the control of beam width and the elimination or reduction of secondary lobes.

The simplest arrays use $\lambda/2$ electric dipoles with half spacings of $\lambda/2$, an arrangement closely approximating a continuous sheet distribution of currents. This
Fig. 67. Simple pattern switching by addition of odd and even pattern functions from separate sets of radiators.

"arrangement" provides convenient impedances and convenient feeder systems. For the same reasons, it is desirable to treat radiators in pairs rather than singly, and the formulas given below are in that form. Other spacings can be used and occasionally are.

In arrays of this sort, the pairs with the greater spacings produce the greatest influence on the sharpness of the main lobe in an equal-current distribution, but they also contribute to the production of large secondary lobes. In radar applications particularly, these secondary lobes are undesirable or positively detrimental, even though the power involved may be small.

Binomial distributions are produced when the radiator currents are graded symmetrically from center as follows:[3]

Array length, λ	No. pairs	Coefficients for pattern formulas					
		A	B	C	D	E	F
		Current ratios from center					
1½	2	0	1.00	0.33			
2	2½	1.00	0.67	0.16			
2½	3	0	1.00	0.50	0.1		
3	3½	1.00	0.75	0.30	0.05		
3½	4	0	1.00	0.60	0.20	0.1	
4	4½	1.00	0.80	0.40	0.11	0.014	
4½	5	0	1.00	0.67	0.29	0.07	0.008

[1] See references 271, 246, 247, 306, and 320.
[2] See reference 326.
[3] See references 58 and 284.

It will be noted from this table that the current amplitudes decrease very rapidly from center. (In odd numbers of radiators, the maximum current is applied to the center radiator; in even numbers, to the central pair.) Outer pairs therefore function almost solely for side-lobe suppression and the central pairs determine the beam width. Actually, radiators with currents less than 10 per cent of maximum can be deleted with small consequences.

68. Fourier Current Distributions. It is frequently desired to produce a particular pattern shape with side lobes suppressed to some specified maximum value where their effect is negligible. To do this, the desired pattern is Fourier-analyzed in terms of spherical harmonics, much as a distorted wave form is analyzed in terms of ordinary harmonics[1] (see also Dolph-Tchebyscheff current distributions). The coefficients from this Fourier analysis determine the current grading by pairs to be used to realize the desired pattern. The number of terms in an infinite series determines the degree of approximation that the designer wishes to approach his ideal objective.

Radiation Patterns for Symmetrical Arrays of Half-wave Dipoles with Half-wave Spacings, Arranged in Colinear, Linear Parallel, and Rectangular Planar Configurations and Located a Distance X from an Infinite Perfectly Conducting Plane Reflector

1. *Equations of Pattern for m Colinear Pairs of Dipoles, Cophased* (Fig. 63):

$$f(\theta) = \underbrace{\left\{\sum_1^m a_m \cos\left[\frac{(2m-1)\pi}{2}\sin\theta\right]\right\}}_{\text{Array factor}} \left\{\underbrace{\left[\frac{\cos\left(\frac{\pi}{2}\sin\theta\right)}{\cos\theta}\right]}_{\text{Dipole factor}} \underbrace{\left[\cos\left(\frac{2\pi x}{\lambda}\right)\cos\theta - \frac{\pi}{2}\right]}_{\text{Reflector factor}}\right\} \qquad (1)$$

$$f(\phi) = \cos\left(\frac{2\pi x}{\lambda}\cos\phi - \frac{\pi}{2}\right) \qquad (2)$$

2. *Equations for Linear Parallel Array of n Pairs of Dipoles, Cophased* (Fig. 64):

$$f(\phi) = \underbrace{\left\{\sum_1^n A_n \cos\left[\frac{(2n-1)\pi}{2}\sin\phi\right]\right\}}_{\text{Array factor}} \underbrace{\left\{\cos\left[\frac{2\pi x}{\lambda}\cos\phi - \frac{\pi}{2}\right]\right\}}_{\text{Reflector factor}} \qquad (3)$$

$$f(\theta) = \underbrace{\left[\frac{\cos\left(\frac{\pi}{2}\sin\theta\right)}{\cos\theta}\right]}_{\text{Dipole factor}} \underbrace{\left[\cos\left(\frac{2\pi x}{\lambda}\cos\theta - \frac{\pi}{2}\right)\right]}_{\text{Reflector factor}} \qquad (4)$$

3. *Planar Array of n Pairs of Rows of m Pairs of Colinear Dipoles, Cophased* (Fig. 65):

$$f(\theta) \equiv \text{Eq. (1)}$$
$$f(\phi) \equiv \text{Eq. (3)}$$

[1] See references 271 and 326.

4. *Lobe-switched Beaver-tail Pattern for Array of Parallel Dipoles, Using n Pairs of Cophased Elements and k Pairs of Interlaced Antiphased Elements* (Fig. 66a):

$$f(\phi) = \left\{ \sum_{1}^{n} A_n \cos\left[\frac{(2n-1)\pi}{2}\sin\phi\right] \right.$$

Even-array factor

$$\left. \pm\, C \sum_{1}^{k} B_k \cos\left[k\pi \sin\phi - \frac{\pi}{2}\right]\right\} \left\{\cos\left[\frac{2\pi x}{\lambda}\cos\phi - \frac{\pi}{2}\right]\right\} \quad (5)$$

Odd-array factor — Reflector factor

$f(\theta) \equiv$ Eq. (4)

5. *Conical Scanning of Ellipsoidal Pattern for Planar Array of n Pairs of Parallel Rows of m Pairs of Colinear Dipoles, Cophased, Interlaced with k Pairs of Parallel Rows of Colinear Dipoles Having l Pairs, Antiphased* (Fig. 66b):

$f(\phi) \equiv$ Eq. (5)

$$f(\theta) = \left\{ \sum_{1}^{m} a_m \cos\left[\frac{(2m-1)\pi}{2}\sin\theta\right] \pm D \sum_{1}^{l} b_l \cos\left[l\pi\sin\theta - \frac{\pi}{2}\right]\right\}$$

Even-array factor — Odd-array factor

$$\left\{\left[\frac{\cos\left(\frac{\pi}{2}\sin\theta\right)}{\cos\theta}\right]\left[\cos\left(\frac{2\pi x}{\lambda}\cos\theta - \frac{\pi}{2}\right)\right]\right\} \quad (6)$$

Dipole factor — Reflector factor

Sequence of switching of antiphased feeders below: C and D are usually equal. The magnitude of the odd-array factor is usually less than that of the even-array factor, by adjustment of the value of C or D.

In these equations, θ and ϕ are measured from the normal to the plane of the array. θ is the angle in the meridian plane (E plane) and ϕ is the equatorial plane of the dipole (H plane).

Interval	C	D
1	+	+
2	−	+
3	−	−
4	+	−
1	+	+

A_n, a_m, B_k, and b_l are Fourier, binomial, uniform, or other systematic coefficients for the current distributions in successive pairs of radiators to obtain desired pattern shapes.

69. Flat Reflecting Screens. A conducting screen, mesh or sheet, of sufficient area, when placed behind a radiating system, acts as a reflecting surface.[1] Use is made of this fact in v-h-f flat arrays. There is diffraction around its edges which sets up fields in the rear of the reflector, and the size used is chosen to keep the stray fields below certain values, depending upon the application. The size is empirical, but in general the higher the directivity of the radiating system, the smaller can be the projecting dimensions of the reflector. In electrically large arrays, the dimensions of the reflector have been as little as $\lambda/2$ more than the radiating system in both length and width. The reflector size depends also on the spacing from the radiators, but this is unimportant for the usual spacings of from 0.1 to 0.25λ. When screens made of wire grids are used, the wires are parallel to the radiators. The spacing between grid wires can be as large as 0.2λ for acceptable forward effectiveness; for better suppression to the rear, smaller spacings are necessary. Designs requiring a high degree of suppression of backward radiation use spacings as small as 0.05λ. The same is true of square mesh

[1] See reference 119.
FIG. 68. Transmitting antenna in front of flat sheet. F_t is the field intensity with reflector; F_0 is the field intensity from a free-space dipole; R_m is the mutual impedance between the dipole and its reflector image; R_{00} is the self-resistance of the free-space dipole.
FIG. 69. Receiving antenna in front of flat sheet. I_0' = dipole current without the reflector. I_0 = dipole current with the reflector present.

screens. Screens are preferred to continuous metallic sheets for arrays exposed to winds.

Figure 68 shows the ratio of forward field with a continuous metallic reflector to that without a reflector as a function of spacing for the transmitting case. Figure 69 shows the ratio of received antenna currents with and without a reflector. These approximate the results with screens and grids of finite dimensions.[1]

[1] See reference 119.

70. V-h-f Antenna Measurements. Performance measurements on v-h-f antennas consist principally of (1) measurement of the radiation pattern and (2) measurement of the impedance at the main feeder by means of observing the standing waves on the feeder to be used with the system. For wide-band systems, these are repeated throughout the range of frequencies to be accommodated.

Pattern measurements are made by energizing the radiating system and rotating it on a turntable while observing the field intensity on a recorder at a fixed point. The
FIG. 70. Curves useful for determining nulls in patterns.

field strength vs. angle is thus examined through 360 deg. Patterns at any orientation can be measured in this way. Errors of large magnitude result when the receiving equipment is moved around a fixed transmitting antenna. The location used should be open and free of objects which will produce reflections in the direction of the receiver, and the receiving antenna should be highly directive toward the turntable and discriminate as much as possible against pickup from the sides. The amplitude response of the detector used must be known so that corrections can be computed for its curvature influence on the observed values. A linear detector indicates relative field intensities directly, and a square-law detector indicates relative power directly. Most detectors fall between these limits, and their empirical results must be corrected.

Incorrect patterns indicate incorrect amplitudes and phases of the currents in the radiators. Improper impedance matches in the feeders must then be located by analysis and corrected. Very little can be done by direct measurement at these feeders, and the final results must be achieved by measurement of the pattern.

The input impedance to the array can be measured by the slotted-line technique or other suitable impedance-measuring instrument.

The band width of an antenna from an input-impedance standpoint is normally determined in terms of some specified standing-wave ratio in the main feeder, assuming virtually perfect match at mid-band. The maximum permitted at the edges of the band depends upon the intended service. For some noncritical applications this can be a standing-wave ratio of 2, while for others it must be as low as 1.1. The standing-wave ratio should be specified when specifying band width.

71. Curves Showing Locations of Nulls in Patterns Such as Fig. 20. In designing directive antennas of various types, use is often made of polar patterns for pairs of radiators, and more extensive arrays are synthesized from such pairs. Figure 70 will be useful in such exploratory work because it shows the angles at which the nulls occur. Interpolation can be made easily between the three phase lines, permitting close estimation of the null positions for any value of phase difference between radiator currents.

72. Values for Certain Basic Patterns for Pairs of Radiators and for the Pattern of the $\lambda/2$ Dipole. Various patterns for extended arrays are synthesized by addition and multiplication of functions for basic elements, among them the $\lambda/2$ dipole pattern and the patterns for certain pairs of radiators. Since $\lambda/2$ spacing between elements of a pair is most frequent in practice, owing to ease of feeding an array, there are tabulated below such combinations as are usually required for cophased and antiphased pairs with integral multiples of the $\lambda/2$ spacing and for the action of neutral reflectors. With these tables, many of the broadside beam antenna patterns can be quickly calculated, including those using various systems of current grading between successive pairs, for both odd and even functions.

S-H-F (MICROWAVE) ANTENNAS (3 TO 30 KMC)

The microwave region is one of transition from the region in which the wavelength is large compared with the dimensions of the components of the system to the optical region in which the wavelengths are very small.[1] Here the wavelengths are of the order of magnitude of the dimensions of easily handled mechanical devices. This leads to a radical modification of earlier antenna techniques and permits the use of complex antenna structures. The techniques of geometrical optics, as well as the theories used at lower frequencies, can be applied to the design of antennas in this region.

73. Horn Antennas.[2] Horn antennas are expanding wave guides of finite length; a relatively large aperture can be obtained. A number of modes are excited in the throat of the horn because of the junction of the wave guide and flare section. However, if the flare angle is not too large, the higher modes are attenuated to a negligible level before free propagation in the horn space is possible.

Many types of antennas can be classified as horn antennas. A few of the more important are shown in Fig. 71. The *sectoral* and *pyramidal horns*[3] have rectangular cross sections and are fed from a rectangular wave guide carrying the dominant $TE_{1,0}$ mode. The *conical horn*[4] has a circular cross section and is fed from a circular guide carrying the $TE_{1,1}$ mode. *Biconical horns*[5] are biconical antennas with large cone angles and hence produce omnidirectional radiation in the plane perpendicular to the cone axes. The *discone antenna*[6] can also be classed as a type of biconical horn.

cos (X sin φ + 90) for −φ angles all signs are reverse of those shown

The sectoral horn is flared in one dimension only, either in the plane parallel to the electric vector (E plane) or in the plane parallel to the magnetic vector (H plane). Such a horn produces a fan-shaped beam sharp in the plane of the flare and broad in the orthogonal plane.

Horns are often used where antennas with medium directive gains are required. For example, a pyramidal horn with a directivity of 400 (26 db) will be approximately
FIG. 71. Types of rectangular and circular horn antennas.

20λ long (which at X band is about 2 ft). Horns are used as highly accurate secondary standards of directive gain because the measured and theoretical values are in very close agreement. They are also employed as the primary feed to illuminate a reflector or lens. In this case the input impedance and efficiency of illumination, rather than directive gain of the horn, are of primary importance.

For small flare angles the field-strength variations across the aperture of a rectangular horn are similar to the variations of the $TE_{1,0}$ mode across the rectangular wave guide feeding the horn. Therefore the aperture field is essentially uniform in magnitude in the E plane and sinusoidally distributed in magnitude in the H plane. This is

the assumption used in pattern calculations, and its validity is borne out in practice by the radiation patterns that result in the E and H planes.

To ensure in-phase fields across the aperture, and therefore high directivity, a very long horn with small flare angle is required; practically, this is inconvenient. An *optimum* horn is defined as one for which the flare angle(s) are chosen so that, for a given length of horn, the directivity is a maximum. For a given horn length, the aperture area, hence directivity, increases with the flare angle. However, beyond a certain flare angle this is overshadowed by phase-error effects in the aperture. If the slant length of the horn is l, the aperture A, and the flare angle θ, as shown in Fig. 72, the difference in path length between the center and edge δ is

$$\delta = l(1 - \cos \theta/2) \doteq A^2/8l$$

FIG. 72. Phase error in the aperture of a horn antenna.

The corresponding phase difference is very nearly $\beta_0\delta$ because the wavelength at the mouth of the horn is essentially equal to the free-space wavelength (β_0 = free-space phase constant). This is the fundamental limitation of all horn antennas.

To a first approximation, δ for optimum horns is independent of the directivity of the horn but is different for the various types of horns. A table of approximate values of δ for optimum horns obtained from theory and measurement is given below.[1]

Type of Horn	δ
H-plane sectoral, or H plane of pyramidal horn	0.40
E-plane sectoral, or E plane of pyramidal horn	0.25
Conical horn	0.32

Note that the tolerance in the H plane is greater than for the E plane. This is true because the contributions from the fields near the sides of the horn to the radiated field are considerably less in the H plane than in the E plane because of the sinusoidal H-plane distribution.

It has been found that, if the aperture in both planes is greater than about 1 to 2λ, the pattern in one plane is essentially independent of the aperture dimensions in the other plane. A set of radiation patterns of pyramidal-horn antennas has been measured as a function of the E-plane flare angle θ, H-plane flare angle ϕ (from 0 to 50 deg), and radial length of the horn R (from 0 to 50λ).[2] These are shown in Figs. 73 and 74. All patterns have been normalized to the same maximum value, hence give no indication of relative directivity. These figures indicate the variety of patterns that can be obtained from a horn antenna and can serve as a guide in horn design. The pattern band width for a particular horn design can be determined from the patterns. Since the radiation patterns in one plane are independent of the aperture dimensions in the other plane these patterns are also applicable to E-plane and H-plane sectoral horns.

Approximate expression for the half-power beam width and the beam width between nulls of the main beam in degrees for optimum horns with relative large apertures are given below.[3] The E- and H-plane beam widths of an optimum pyramidal horn can be found from the formulas for the respective sectoral horn.

Horn	Angle between nulls, deg	Angle between half-power points, deg
Optimum E-plane sectoral horn	$115\lambda/b$	$56\lambda/b$
Optimum H-plane sectoral horn	$172\lambda/a$	$67\lambda/a$
Optimum conical horn:		
E plane	...	60λ/diam
H plane	......	70λ/diam

[1] See references 9 and 355.
[2] See reference 369.
[3] See references 9 (p. 380) and 355.
FIG. 73. Electric-plane patterns of a rectangular horn antenna as a function of radial horn length R and E-plane flare angle θ.

The field radiated by a properly constructed rectangular horn is linearly polarized. In the E and H planes the direction of polarization is parallel to the electric field in the aperture. Circular polarization can be obtained if a square horn is fed from a square wave guide propagating orthogonal (space and time) TE modes.

The directivity of a horn antenna can be calculated quite accurately from the physical dimensions of the horn and use of curves or tables.[1] These data are based upon the

[1] See references 12, 330, and 351.
FIG. 74. Magnetic-plane patterns of a rectangular horn antenna as a function of radial horn length R and H-plane flare angle ϕ.

assumption that the field in the horn aperture is the same as though the sides were infinitely long. Experimental measurements have indicated that the error due to this assumption is negligibly small.

The directivity of a horn antenna may be determined with the aid of the tables[1] given below and Figs. 75 to 77. To find the directivity of a pyramidal horn calculate the quantities

$$A = a\sqrt{50/l_H} \qquad \text{and} \qquad B = b\sqrt{50/l_E}$$

[1] See reference 331.

where a = H-plane aperture dimension in free-space wavelengths
b = E-plane aperture dimension in free-space wavelengths
l_H = H-plane slant length in free-space wavelengths
l_E = E-plane slant length in free-space wavelengths
and find the corresponding values for G_H and G_E in the tables for the proper values of A and B, respectively. Then the directivity g is given by

$$g = \frac{G_E G_H}{\frac{32}{\pi}\sqrt{50/l_H}\sqrt{50/l_E}}$$

For an H-plane sectoral horn calculate

$$A = a\sqrt{50/l_H}$$

and find G_H from the tables. Then,

$$g_H = \frac{bG_H}{\sqrt{50/l_H}}$$

For an E-plane sectoral horn calculate

$$B = b\sqrt{50/l_E}$$

and find G_E from the tables. Then,

$$g_E = \frac{aG_E}{\sqrt{50/l_E}}$$

The directivity of an *optimum* H-plane sectoral horn is

$$g_H = 7.86\ ab$$

and the directivity of an *optimum* E-plane sectoral horn is

$$g_E = 8.0\ ab$$

The directivity of a large uniformly illuminated rectangular aperture of dimensions a and b (in wavelengths) is $g_0 = 4\pi ab$. Hence, the directivity of the sectoral horns relative to the uniformly illuminated aperture (sometimes called *aperture efficiency*) is approximately
Fig. 76. Dimensions of the H-plane sectoral-horn antenna.
Fig. 77. Dimensions of the E-plane sectoral-horn antenna.

0.62 (62 per cent) for the optimum H-plane horn and 0.64 (64 per cent) for the optimum E-plane horn.

Since horn antennas are nonresonant structures, they present a fairly good termination for wave guides over a broad band of frequencies. The input admittance observed in the wave-guide feed depends upon the admittance of the aperture, the transforming properties of the flared section, and the transforming properties of the junction with the wave guide.[1]

If a horn is to be used in a communications system, the important considerations are usually maximum directivity and minimum size (*i.e.*, an optimum horn), while if a horn is to be used as a primary feed, the efficiency of illumination of the reflector or lens, not directivity, is important. There are other applications where the important design considerations differ from these two. For example, in the field of antenna measurements it is usually required that a horn be designed to illuminate a specified sector at a minimum range with a minimum of variation in amplitude (and phase).

74. Horn Design. A procedure for designing an optimum pyramidal horn whose sides meet the wave guide in a common plane is as follows.[2] If the directivity g is specified, then the dimensions of the horn in the E plane are

$$b = 0.346\sqrt{g}$$
$$l_E = 0.0576g$$
$$\sin\frac{\theta}{2} = \frac{b}{2l_E} = \frac{3.0}{\sqrt{g}}$$

In the H plane the dimensions are

$$a = 0.468\sqrt{g}$$
$$l_H = \frac{a}{a - w_H}\sqrt{\left[l_E^2 - \left(\frac{b}{2}\right)^2\right]\left[\frac{b - w_E}{b}\right]^2 + \left[\frac{a - w_H}{2}\right]^2}$$
$$\sin\frac{\phi}{2} = \frac{a}{2l_H}$$

where a = H-plane aperture dimension
b = E-plane aperture dimension
l_H = H-plane slant length
l_E = E-plane slant length
ϕ = flare angle in H plane
θ = flare angle in E plane
w_H = H-plane wave-guide width
w_E = E-plane wave-guide width

Note that all these dimensions, and the rest in the design section, are inside dimensions (ID) and are expressed in wavelengths.

To accomplish a union between the flared horn section and the wave guide at a common plane, the H-plane dimension in this procedure has been altered slightly from the optimum dimension. This reduces the directivity in the H plane and the over-all directivity. The reduction is slight, however, and can be taken into account by using a directivity 4 to 5 per cent higher than that desired.

The axial length L of this horn from the plane of the junction with the wave guide to the plane of the aperture is

$$L = \frac{b - w_E}{b}\sqrt{l_E^2 - \left(\frac{b}{2}\right)^2}$$

or

$$L = \frac{a - w_H}{a}\sqrt{l_H^2 - \left(\frac{a}{2}\right)^2}$$

The length along a common edge R between wave-guide junction and aperture is

$$R = \frac{b - w_E}{b}\sqrt{l_E^2 + \left(\frac{a - w_H}{2}\right)^2}$$

[1] See reference 15.
[2] See reference 331.

The slant length of the horn section along l_H between the aperture and the wave-guide junction is

$$\frac{b - w_E}{b} \sqrt{l_E^2 - \left(\frac{b}{2}\right)^2 + \left(\frac{a - w_H}{2}\right)^2}$$

and along l_E is

$$\frac{a - w_H}{a} \sqrt{l_H^2 - \left(\frac{a}{2}\right)^2 + \left(\frac{b - w_E}{2}\right)^2}$$

A procedure for designing *optimum* sectoral horns can be evolved as follows. Consider first an H-plane horn. The directivity of an optimum H-plane sectoral horn is

$$g_H = 7.86ab$$

where a = H-plane aperture dimensions
b = E-plane aperture dimensions = w_E (all dimensions are ID in wavelengths)
If the directivity is specified,

$$a = g_H/7.86w_E$$

The path length δ_H for an optimum H-plane sectoral horn is 0.397. Therefore,

$$\delta \doteq 0.397 \doteq a^2/8l_H$$

or

$$l_H \doteq a^2/3.18$$

The axial length between the plane of the junction of the wave guide and the plane of the aperture is

$$L_H = \frac{a - w_H}{a} \sqrt{l_H^2 - \left(\frac{a}{2}\right)^2}$$

Likewise, the directivity of an *optimum* E-plane sectoral horn is

$$g_E = 8.0ab$$

where a = H-plane aperture dimension = w_H
b = E-plane aperture dimension (all dimensions are ID in wavelengths)
If the directivity is specified,

$$b = g_E/8w_H$$

For an E-plane optimum horn $\delta_E \doteq 0.25$; therefore,

$$\delta_E \doteq 0.25 \doteq b^2/8l_E$$

or

$$l_E \doteq b^2/2.0$$

The axial length between the plane of the junction with the wave guide and the plane of the aperture is

$$L_E = \frac{b - w_E}{b} \sqrt{l_E^2 - \left(\frac{b}{2}\right)^2}$$

The shape (side-lobe level and beam width) of the E-plane and/or H-plane patterns of these antennas can be obtained by reference to Figs. 73 and 74.

When small horns are used as feeds for paraboloidal reflectors, an important characteristic is the 10-db (tenth-power) beam width of the radiation pattern. Empirical formulas that can be used as a good first approximation in the design of horn feeds are (the average flare angle is about 20 deg)[1]

$$H\text{-plane 10-db BW} = 31 + 79/a \quad \text{deg } (a < 3.0)$$
$$E\text{-plane 10-db BW} = 88/b \quad \text{deg } (b < 2.5)$$

where a = H-plane aperture dimension
b = E-plane aperture dimension (all dimensions are ID in wavelengths)

[1] See reference 15.

75. Parabolic-reflector Antennas.[1] Narrow-beam antennas require a radiating aperture which is very large compared with the wavelength. The parabolic-reflector antenna is a simple and convenient device to achieve this. It will operate over a relatively large band of frequencies; the band width is usually determined by the characteristics of the primary feed and the reflections from the surface back into the feed.

In principle, the parabolic-reflector antenna has the property of producing a plane wave front over its aperture from a point source located at its focus. This can be shown as follows. To produce a plane wave front from the reflecting surface shown in Fig. 78, the electrical distance from the point source to a plane perpendicular to the axis of the reflector along any two paths must be equal. For example, the distance from the point source at F to O and back must equal the distance FAB, that is
FIG. 78. Dimensions of the parabolic-reflector antenna.

$$2f = r(1 + \cos\theta)$$

or

$$r = 2f/(1 + \cos\theta)$$

This is the standard equation of a parabola in polar coordinates with its focus at the origin where f is defined as the focal length. In cartesian coordinates the standard equation with the origin at the vertex is $y^2 = 4fx$. Hence, the reflecting surface must be parabolic in shape.

A parabolic-cylinder reflector converts cylindrical waves from a line source at the focus into plane waves at the aperture. (Special types of parabolic-cylinder reflectors are used where accurately shaped patterns are required.) Antennas of this type are generally used where maximum directivity from an aperture is required and have been extensively employed in radars, both air-borne and ground-based, and recently in tropospheric-scatter communications systems and for radio astronomy. To achieve high directivity and maximum efficiency from the antenna, close control of the radiation from the primary feed illuminating the surface is required. That is, the primary feed must be small, produce spherical phase fronts, adequately illuminate the entire reflector surface without excess "spill-over," and produce such a field that after reflection the waves will be properly polarized. Some of these requirements are contradictory and compromises have to be made.

If the phase fronts of the radiation from the primary feed are not spherical, the wave fronts after reflection are not plane and the radiation pattern will be distorted and the directivity of the antenna reduced. The main effect of phase errors over the aperture, with common aperture distributions, is, in general, to reduce the gain and broaden the main lobe, particularly at the lower levels. The side-lobe level may be either raised or lowered depending upon the type of phase distortion and the intensity (amplitude) distribution over the aperture. Generally the nulls between the side lobes are filled in and their levels raised. Severe phase errors may result in splitting of the main lobe and a large increase in the side-lobe level.

To make the most effective use of the aperture of the parabolic-reflector antenna (*i.e.*, to obtain maximum directivity), the energy radiated from the primary source must be distributed uniformly over the surface. Practically, however, this is impossible without loss of energy due to "spill-over." Energy not intercepted by the reflector contributes to the side-lobe region and reduces the directivity of the point-source reflector-antenna system. Likewise, if the aperture illumination is tapered down in magnitude toward the edge to zero to reduce "spill-over," the directivity of the antenna again decreases. Therefore, somewhere between the uniform amplitude illumination and the zero-edge taper is an optimum amplitude distribution for maximum directivity. The ratio of the directivity of the parabolic-reflector antenna to the directivity of a uniformly illuminated aperture of the same area, which has the highest

[1] See references 9, 15, 341, and 360.

gain for uniform phase distribution, can be used to express the efficiency of the antenna illumination. This ratio is the directivity of the parabolic reflector relative to a uniformly illuminated aperture of the same area and depends upon the shape of the radiation pattern of the primary feed. It has been found experimentally that maximum directivity can be obtained for a circular paraboloid when the beam width to the −10-db points on the primary pattern corresponds to the angle subtended by the reflector at the focus. It is not critical, however. For a well-designed antenna, this maximum directivity is approximately 65 per cent of that of a uniformly illuminated circular aperture. To state it in another way, the effective aperture of a well-designed paraboloidal-reflector antenna is about 65 per cent of the projected area of the reflector. The incident energy at the edge of the reflection in this case is further reduced because of the increased space attenuation in the longer path. Figure 79 illustrates the tapering of the aperture illumination with an isotropic point, or line, source at the focus and can be used to determine the edge illumination.

Fig. 79. Aperture illumination of the parabolic-reflector antenna due to an isotropic radiator at the focus.

From the above considerations an order of magnitude of the directivity of a large practical paraboloidal reflector with the optimum amplitude illumination can be obtained as follows. The directivity of a large uniformly illuminated aperture is $4\pi \times \text{area}/\lambda^2$. For a large circular aperture of diameter d, this becomes $(\pi d/\lambda)^2$, and so the maximum directivity g of a large paraboloidal reflector is

$$g \doteq 6(d/\lambda)^2$$

The radiation pattern of a uniformly illuminated circular aperture has a half-power beam width of approximately $58\lambda/d$ deg with the first (and highest) side lobe 17.5 db below the main lobe. Beam widths of practical paraboloidal reflectors have been determined empirically (to within 10 per cent) and are shown below.[1]

$$\text{10-db beam width} = 130\lambda/d$$
$$\text{6-db beam width} = 100\lambda/d$$
$$\text{3-db beam width} = 70\lambda/d$$

The side-lobe levels that would be predicted from the diffraction pattern of the aperture of the antenna are often less than the direct radiation from the primary feed and the scattering from inaccurate reflectors and supporting structures used in practice.[2] The surface tolerance depends greatly upon the application. It has been found that for normal purposes a deviation of $\pm\lambda/8$ from the true contour is permissible. However, if the reflector is to be designed to produce low side lobes or a shaped beam,

[1] See reference 360.
[2] See references 334 and 347.

then a deviation of about $\pm\lambda/30$ is required. A tolerance of less than $\lambda/16$ at 8.5-mm wavelength (*i.e.*, 0.010 in.) from the true contour was held in the construction of the 50-ft "Big Dish" at the Naval Research Laboratory for use in radio astronomy.[1]

Feed lines to the primary radiator and support bars should run parallel to the H lines of the field; *i.e.*, there should be no component of E parallel to metal if possible. The best way to determine the effect of supports is to measure the directivity with and without them.

A simple paraboloidal-reflector antenna can be designed using the preceding information as follows. If the gain is specified, the diameter d of the reflector can be determined from the above considerations. The focal length can be determined from the 10-db beam width, $2\theta_{10}$, of the primary pattern and the equation of the parabola in polar form. That is, $f = [d(1 + \cos\theta_{10})]/[4 \sin\theta_{10}]$. If required, the diffraction pattern of the aperture can be calculated from the actual aperture distribution, which can be obtained from the primary pattern and Fig. 79. If low side lobes are important a greater amplitude taper can be used, or if high directivity is most important a more uniform illumination can be used.
Fig. 80. Electric field in the parabolic-reflector aperture and resulting far-zone radiation patterns when the paraboloid is excited by a vertically oriented electric dipole.

76. Practical Primary Source Feeds for Parabolic-reflector Antennas.[2] The general requirements of a feed for a paraboloidal-reflector antenna are, as stated previously: (1) the feed must be small so that it appears as a point source, and to avoid excessive scattering from it, (2) it should produce spherical equiphase surfaces, (3) it must have the proper polarization characteristics, and (4) it should efficiently illuminate the entire reflecting surface. The shape of the pattern from it is limited, however, by the necessity to keep it small.

In addition, the input impedance of the feed must match that of the transmission line over as broad a band of frequencies as possible. The limits are determined by the application. For example, the impedance band width of a transmitting antenna is usually taken to be the band of frequencies over which the SWR is less than 1.5. The power-handling capacity of the feed is another important consideration. This is limited by the electrical breakdown between component parts and is of particular significance in aircraft antennas because the decrease in atmospheric pressure and the increase of free-ion content cause a decrease in breakdown potential with altitude. Therefore, feeds for aircraft antennas must be pressurized. The feed should be mechanically strong yet lightweight, and its design must specify reasonable tolerances so production methods can be used in its construction.

Both front and rear feeds are used. Front feeds are simpler electrically; rear feeds are simpler mechanically. Offset feeds are sometimes employed to remove the feed from the high-intensity fields.

The polarization characteristics of the primary radiator should be such that the waves will be polarized in the same direction after reflection from the paraboloid surface. Field components which are polarized perpendicular to the average are wasted

[1] See reference 350.
[2] See references 15, 341, and 360.

and contribute to side-lobe radiation. It has been shown theoretically that either electric-dipole- or magnetic-dipole-type feeds produce a field configuration in the aperture of a paraboloidal reflector that results in cross-polarized side lobes with a maximum in the planes at 45 deg to the principal planes,[1] as shown in Figs. 80 and 81. If a plane-wave field is used (*i.e.*, the proper combination of electric and magnetic dipoles), the aperture field configuration is such that the radiated field has only one field component, as shown in Fig. 82. In this case the E- and H-plane patterns of the feed are equal and patterns in the other planes are very similar, and therefore the
Fig. 81. Electric field in paraboloid-reflector aperture when paraboloid is excited by a short magnetic dipole lying along the y axis.
Fig. 82. Electric field in paraboloid-reflector aperture when paraboloid is excited by a small plane-wave source polarized along x axis.

main beam from the reflector has nearly a circular cross section. In practice, a horn-feed approximation to a plane-wave feed produced cross-polarized side lobes in the planes 45 deg to the principal planes at least 25 db below the principal-plane maximum.

77. Feed Systems. The most commonly used rear feeds are electric dipoles with parasitically excited reflectors, the dual-aperture (Cutler) feed, and the two-dipole wave-guide feed. Small horns, including open-ended wave guides, are generally used as front feeds.

78. Dipole Feed. Electric-dipole feeds are generally employed at frequencies where coaxial transmission lines are used. Electric dipoles used without reflectors are not suitable feeds because the pattern is uniform in the plane perpendicular to its length (H plane) but nonuniform ("figure-eight" pattern) in the planes that include its length; hence half or more of its radiated energy is not directed toward the surface. To increase the directivity of the primary pattern, dipoles are used with tuned-wire reflectors, plane-sheet (disk), half-cylinder, and hemispherical reflectors. For example, a dipole and a parasitically excited element tuned to a reactance of about 30 ohms and located $\lambda/8$ behind the driven element to act as a reflector are commonly used. A reflecting disk at least $\lambda/2$ in diameter is used with spacings up to 0.4λ. Since the spacing in this case is not too critical it is used in matching the dipole to the feed line. Even
Fig. 83. Two methods of exciting balanced currents on a dipole feed.

[1] See references 341 and 353.

when used with a reflector, dipole feeds are limited by the range of patterns that can be obtained. Another disadvantage is the problem of feeding the dipole with balanced currents from an unbalanced (coaxial) line without producing currents on the outside of the outer conductor which cause spurious radiation. Various types of baluns (balance-to-unbalance transformers) can be used to overcome this effect. Two methods commonly used are the *quarter-wave-length skirt* and the *slot-balancing stub*, which are shown in Fig. 83.[1]

The power-handling requirements must also be considered in the design of dipole feeds. The parts of the dipole must be sufficiently spaced to prevent arc-over, and sharp corners must be avoided. Radiation from widely spaced slot-balancing systems seriously distorts the pattern of the feed, and shielding by a metal can is required. In general, design data for dipole feeds must be obtained experimentally because of the difficulty of predicting the properties theoretically.

Fig. 84. Wide-band dipole for the 50- to 60-cm band.

To obtain minimum cross-polarization effects and the best aperture distribution using a dipole-type feed, it has been found that the reflector should subtend an angle of about 140 deg at the focus.

79. Matching Problems. Two factors contribute to the mismatch at the input terminals of any feed: (1) the mismatch caused by the feed itself and (2) reflections from the reflecting surface of the antenna back into the feed. These are usually treated separately. The impedance of dipole-type feeds cannot be predicted with any degree of accuracy; so variation in impedance with frequency must be determined from measurements. Narrow-band impedance matching consists in varying the length of the driven dipole to tune out the reactance, and then using a $\lambda/4$ transformer to match the feed line. Broad-band matching at the higher frequencies has been accomplished by using thick dipole elements (tapered at the feed end to reduce capacitance) since the change in reactance with frequency is less for thick dipoles. Stub compensation can also be used.

At the lower frequencies, where dipole feeds are used almost exclusively, stub compensation is used to increase the band width.[1] This is accomplished as follows. First the dipole length is adjusted until its conductance at mid-band is equal to that of the feed line, and then the susceptance is removed with a shorted stub in parallel with the dipole, as shown in Fig. 84. Then, as the frequency changes, the susceptances of the dipole and stub vary in opposite directions. By adjusting the characteristic impedance of the stub and its length (by adding half wavelengths) it is possible to get good compensation over a frequency band.[2]

80. Wave-guide Feed. At centimeter wavelengths wave-guide feeds are practical. The two-dipole wave-guide-type feed shown in Fig. 85 has been extensively used because it is much simpler to feed a dipole from a wave guide than from a coaxial line.[3] The dipoles are mounted on a web that fits into the mouth of the wave guide so the dipoles are parallel to the electric field of the dominant $TE_{1,0}$ mode. Equal excitation is achieved if the web is symmetrically located. The combination is tuned to reflect

[1] See reference 360.
[2] See reference 372.
[3] See reference 15, p. 255.

power back into the reflecting surface. The closest dipole is resonant; the second dipole acts as a parasitic element. The second dipole can be replaced by a disk. The wave guide is tapered to serve as an impedance-matching device. It also improves the radiation pattern because it helps decouple the outer wall from the dipole. The impedance of the antenna is also determined by the depth of the web and the position of the dipoles with respect to the mouth.

Another wave-guide feed is the *dual-aperture rear feed* (*Cutler feed*)[1] which essentially splits the energy in the wave guide into two branches that turn back on themselves
Fig. 85. Wave-guide couple-dipole feed; $\lambda = 3.2$ cm.

and radiate toward the reflector through two slots. A sketch is shown in Fig. 86. It is important that the two apertures be less than $\lambda/2$ apart and that the apertures be not too close to the wave-guide wall. Therefore, the wave guide must be tapered to something less than $\lambda/4$ in the narrow dimension. The two branch paths are contained in a cylindrical cavity. The dimensions of the cavity and the indentation at its center can be used in matching the feed to the wave guide. This is usually determined by experiment. Band widths of 6 per cent have been obtained at X band for an SWR less than 1.3. The phase front on either side appears to be coming from the nearer aperture and its image to be reflected in the wave-guide wall. This results in phases in the E and H planes at the edge of the reflector which differ by about 30 deg.

[1] See reference 341.

The shape of the pattern in the *E* plane can be controlled by the separation of the slot from the wave-guide wall and somewhat by slot width. The *H*-plane pattern can be controlled by the length of the slot.

Recently, a wave-guide feed having equal *E*- and *H*-plane radiation patterns has been developed.[1] The feed consists of an electric-dipole source and a parasitically excited open-ended coaxial line carrying a $TE_{1,1}$ mode which is similar to a magnetic-dipole source. These two sources have complementary pattern characteristics and are combined to compensate each other so equal beam widths can be obtained. It is constructed from a rectangular wave guide tapered in the narrow dimension, as shown in Fig. 87. A hole is drilled into the broad face of the wave guide and a bead-supported dipole is centered in the hole. The $TE_{1,1}$ source is obtained by placing a metallic cylinder around the wave guide. The end of the cylinder farthest from the dipole is short-circuited. The dipole excites a $TE_{1,1}$ mode in this irregular coaxial line. The location and length of the cylinder are adjusted for equal beam widths in the *E* and *H* planes. The relative beam widths can be controlled by the length of the cylinder and the location of the short circuit relative to the dipole. Narrow beam widths are obtained for closer short-circuit spacings. Design data are shown in Fig. 88.

FIG. 86. Dual-aperture rear-feed horn.
FIG. 87. Sketch of an antenna feed, and its performance at *X* band.

The impedance of the feed depends upon the position of the wave-guide short circuit beyond the dipole, the length and diameter of the dipole as well as its supporting Teflon bead, and the hole diameter through which the dipole protrudes. These parameters also determine breakdown power so the problem of adjusting parameters reduces itself to obtaining the largest power-handling capacity with the greatest band width. A table of these characteristics follows.

[1] See reference 335.

Hole diam, in.	Bead diam, in.	% band width (SWR less than 1.5)	Breakdown power, kw
0.450	0.500	2	120
0.350	0.500	11	75
0.250	0.500	22	50

81. Front-feed Systems. The most commonly used front feeds are open-ended wave guides and horn antennas. In general, the radiation characteristics of open-ended wave guides depend upon the size and shape of the aperture and the mode or modes propagating in the wave guide. It has been found that for a circular paraboloid a circular wave guide propagating a $TE_{1,1}$ mode has ideal phase and polarization characteristics with suitable directivity (a 10-db beam width of approximately 130 deg in both principal planes).[1] Greater directivity can be obtained by flaring the aperture
FIG. 88. Effect of cylinder length and position on the E- and H-plane beam widths.

into a small conical horn. An open-ended rectangular wave guide propagating a $TE_{1,0}$ mode does not give a circularly symmetric radiation pattern but is suitable for feeding a paraboloidal section which is cut to subtend a wide angle in the E plane and a narrow angle in the H plane. This is because the pattern in the E plane is quite broad with considerable side and back radiation; the H-plane pattern is much more directive with a half-power beam width of about 50 to 60 deg. The pattern shape can be controlled more or less independently by the corresponding aperture dimension. This feed has good phase characteristics and tolerable polarization characteristics. The shape of the E-plane pattern can be improved by the addition of flanges along its wide dimension. The flange can be about $\lambda/2$ wide. Alternatively, the H-plane pattern can be altered by changing the shape of the mouth of the guide.[2]

82. Wave-guide-horn Feed. Where more directivity is required, some form of wave-guide horn may be used.[3] In this case there are two important factors, the location of the center of phase in the E and H planes and the magnitude of the back radiation. For example, a sectoral horn sometimes used as a feed for elliptical paraboloid sections has poor phase characteristics because the phase center in the plane of the flare is near the apex of the flare angle while in the other plane the phase center is at

[1] See reference 341.
[2] See reference 329.
[3] See Sec. 87.

the horn aperture and these may be several wavelengths apart. Since horn feeds are not resonant, the input impedance is close to that of a uniform wave guide and its magnitude does not change rapidly with frequency. The SWR associated with open-ended wave guides of standard dimensions varies from about 1.8 to 3.0 depending upon the aperture size in wavelengths.

A *two-mode horn* or *box-horn feed*[1] has been designed for elliptical paraboloid sections. Two modes $TE_{1,0}$ and $TE_{3,0}$ are excited in an open-ended wave guide by symmetrically terminating a normal-size wave guide in a guide wide enough to support both modes, as shown in Fig. 89. The relative strength of the two modes is controlled by the ratio of the wave-guide widths and the relative phase is controlled by the length of the wide
FIG. 89. Two-anode feed horn.

wave guide. When the relative phase differs by 180 deg, a resultant in-phase field exists across the aperture with almost constant magnitude. In practice these conditions hold for approximately a 10 per cent band of frequencies.

83. Hoghorn Feed. A wave-guide feed that combines the properties of a horn and parabolic reflector is shown in Fig. 90. It is commonly called the hoghorn feed.[2] This type of feed, and its variations, is a compact electromagnetic horn that has a rectangular aperture which may be from 4λ to 15λ long and from 2λ to 3λ wide and produces a fan-shaped beam of from 4 to 15 deg by approximately 25 deg. It is used as a primary feed for a parabolic-cylinder reflector with closed ends (commonly called the *cheese antenna*). Construction details are shown in Fig. 91. The parabolic surface can be obtained from

$$f = 0.70(a - 0.933w)$$

where f = focal length
$a = BC$
w = wave-guide width ED

The E-plane radiation patterns are essentially the same as a sectoral horn of the same size. The pattern is not quite symmetrical in the H plane with a 17-db side lobe on one side only. The direction of maximum radiation is approximately parallel to the parabola axis. The side-lobe level is critically dependent upon the shape of the horn near the focus.

84. Mismatch Due to Feed. In practice, the presence of the feed in the field has a detrimental effect on the characteristics of the reflector antenna, especially if the

[1] See reference 341.
[2] See reference 366.

antenna is to operate over a broad band of frequencies.[1] As stated above, the mismatch at the input terminals of any feed is due to the mismatch caused by the feed itself and the scattering from the surface of the reflector back into the feed. For example, the SWR on the feed line of a matched horn increased to 1.4 when placed at the focus of a reflector. The magnitude of the impedance of a well-matched feed is fairly constant but the phase varies rapidly with frequency because of the long path lengths and can cause instability of the transmitting oscillator. This can be overcome by using a circularly polarized feed (the wave reflected from the parabola is polarized in the opposite sense), by using an offset feed, or by using an *apex-matching plate*.[2] That is, a plate of dielectric is placed at the apex of the paraboloid to produce a signal equal in magnitude but 180 deg out of phase with that scattered from the remainder of the reflector. Since the sources of reflection are nearly the same distance from the focus, the impedance correction is effective over a wide band of frequencies. However, the directivity is decreased and the side-lobe level is increased because of scattering from the plate.
FIG. 90. Simple hoghorn.
FIG. 91. Geometry of hoghorn.

Direct radiation from the feed to the sides and rear can change the directivity of the reflector antenna with frequency, especially with small paraboloids. In such cases the focal length of the parabola should be coordinated with the wavelength to ensure proper phase of rearward radiation. Even in the absence of direct-feed radiation the presence of the feeds has a detrimental effect on the radiation pattern because of aperture blocking and scattering from the surfaces of the feed. The effect is to reduce directivity and increase the level of the side lobes.

Beam scanning with only a small amount of defocusing can be produced by moving the feed laterally away from the focus. For example, the beam can be shifted about

[1] See reference 347.
[2] See reference 307.

twice the half-power beam width with only a 0.5-db decrease in directivity. The beam shift can be doubled if the feed is fixed and the reflector tilted.

85. Lens Antennas. At centimeter wavelengths, optical devices such as lenses may be applied. Since the fundamental function of a lens is to modify the phase fronts from a radiating source, the lens surfaces are designed using the laws of geometrical optics, as in the case of the parabolic reflector. However, the radiation pattern of the antenna must be considered from the standpoint of diffraction theory.

Because of the difference in wavelengths, microwave-lens techniques are free of certain restrictions which apply in the design of optical lenses. Surface tolerances are large; dielectric lenses can be made of relatively soft low-loss plastics; and the lens surfaces can be molded or turned on a lathe. Consequently, the surface need not be spherical but can be cut to contours appropriate to the function of the lens. Metal-plate lenses, likewise, can be produced by ordinary machine-shop methods.[1]

FIG. 92. Dimensions of dielectric-lens antenna.

Lens antennas can be divided into two types: (1) those in which the electrical (optical) path length is increased by the lens medium (called *delay lenses*), such as natural-dielectric and H-plane metal-plate lenses, and (2) those in which the electrical path length is decreased by the medium, such as the E-plane metal-plate lens.

Dielectric lenses may in turn be divided into three groups according to the materials from which they are constructed: (1) lenses of homogeneous isotropic nonmetallic dielectric material, *e.g.*, polystyrene; (2) lenses of dielectric materials of variable or nonuniform dielectric constant (such as the *Luneberg lens*); and (3) lenses of artificial dielectrics.

86. Dielectric-lens Antennas. Lens design is based on two principles of geometrical optics: (1) the principle of equality of electrical (optical) paths along rays between pairs of wave fronts; and (2) Snell's law of refraction. The design procedure is called ray tracing.

To straighten a spherical wave front, the contour of the lens shown in Fig. 92 is

$$R = \frac{(n-1)f}{n\cos\theta - 1}$$

where f = focal length of lens

n = index of refraction of dielectric medium

$$= \sqrt{\frac{\mu\epsilon}{\mu_0\epsilon_0}} = \sqrt{\mu_r\epsilon_r}$$

If $\mu = \mu_0$, $n = \sqrt{\epsilon_r}$, the square root of the relative dielectric constant. In rectangular coordinates the equation of the surface contour is

$$\left[\frac{(n+1)x}{f} - n\right]^2 - \left(\frac{n+1}{n-1}\right)\frac{y^2}{f^2} = 1$$

which is the equation of a hyperbola. If the origin is moved to the vertex, the equation is

$$\left[\frac{(n+1)x}{f} + 1\right]^2 - \left(\frac{n+1}{n-1}\right)\frac{y^2}{f^2} = 1$$

The asymptotic angle θ_a is given by $\cos\theta_a = 1/n$. Since the right-hand surface lens surface is coincident with an equiphase surface it has no effect on the direction of the rays.

For a point-source feed, the lens surface is a spherical hyperbola, and for a line source feed, it is a cylindrical hyperbola. If the angle θ is small, the shape is approximately spherical.

[1] See reference 15.
Neglecting the attenuation in the material and power loss caused by reflections at the surfaces, the power density $P(\rho)$ watts/m², at any point in the aperture of a spherical hyperbolic lens at a distance ρ ($= R \sin \theta$) from the axis, is related to the geometry of the lens and the power pattern $P(\theta)$ of the point-source primary feed (the primary feed is considered a point source because it should be very much smaller than the lens) by

$$P(\rho) = \frac{(n \cos \theta - 1)^3}{(n - 1)^2(n - \cos \theta)} P(\theta)$$

where n = index of refraction.

The corresponding amplitude $A(\rho)$ at any point in the aperture is

$$A(\rho) = \sqrt{P(\rho)} = \frac{1}{n - 1} \sqrt{\frac{(n \cos \theta - 1)^3}{n - \cos \theta}} A(\theta)$$

where $A(\theta)$ = primary field-strength pattern.

For a cylindrical hyperbolic lens, the power density $P(y)$ watts/m² at any point y ($= R \sin \theta$) from the lens axis, in a cross-sectional plane, is

$$P(y) = \frac{(n \cos \theta - 1)^2}{(n - 1)(n - \cos \theta)} P'(\theta)$$

where $P'(\theta)$ = primary power pattern of the line-source feed as a function of θ in the cross-sectional plane.

The corresponding amplitude $A(y)$ at any point y in the aperture is

$$A(y) = \sqrt{P(y)} = \frac{n \cos \theta - 1}{\sqrt{(n - 1)(n - \cos \theta)}} A'(\theta)$$

Hence, the aperture distribution for a given lens can be determined and the radiation pattern calculated when the primary pattern of the feed is known.

The amplitude functions given above drop off rapidly with θ. For example, for a "spherical" lens of polystyrene ($n = 1.6$), the amplitude has dropped off 50 per cent (6 db) at angles 30 deg from the axis. Larger angles than this result in a high degree of taper to the illumination and a consequent reduction in directivity relative to a uniformly illuminated aperture. For a nearly uniform illumination, therefore, the angle θ must be kept fairly small.

The most serious disadvantage of dielectric lenses of conventional design is their large mass. The dimension of the simple lens described above can be obtained as follows. If (R_m, θ_m) are the polar coordinates of the edge of the lens and t is the lens thickness on the axis, then from the principle of equality of electrical paths

$$t = \frac{R_m(1 - \cos \theta_m)}{n - 1}$$

where n = index of refraction.

A lightweight short-focal-length lens can be obtained by the process of *zoning*, which results in the cross section of Fig. 93. The thickness of a zoned step z is such that the electrical length of z in the dielectric is an integral number of wavelengths (usually taken as one) longer than the electrical length in air. That is, $z/\lambda_d - z/\lambda_0 = 1$, or

$$z = \frac{\lambda_0}{n - 1}$$

where λ_d = wavelength measured in dielectric

λ_0 = wavelength measured in air

Hence, the thickness of a zoned lens will be slightly larger than $\lambda_0/(n - 1)$.

The zoned lens is frequency-sensitive. An approximate expression for the band

width for which the phase variations in the wave front from a plane do not exceed $\lambda/8$ is
Fig. 93. Zoned-lens antenna.

$$\text{Band width} \doteq \frac{25}{K - 1} \quad \text{per cent}$$

where K = number of zones. The zone on the axis is counted as the first zone.

Reflections from dielectric surfaces can cause feed mismatch and power instability and are most likely to occur when a lens surface coincides with an equiphase surface, *e.g.*, the right-hand surface of the simple dielectric lens. The surface-reflection coefficient R at normal incidence is

$$R = -\frac{n - 1}{n + 1}$$

The magnitude of the reflection coefficient increases with n. The lens may be tilted slightly so that the reflected wave comes to focus to one side of the feed without seriously affecting the performance of the lens.

The magnitude of the reflection coefficient also depends upon the angle of incidence. The power loss caused by these reflections reduces the antenna gain and increases the side-lobe level. Figure 94 gives the fraction of the incident power $(R)^2$ reflected from the surface of an infinite slab of dielectric ($n = 1.6$) as a function of the angle of incidence for polarization (1) perpendicular to the plane of incidence and (2) parallel to the plane of incidence. A $\lambda/4$ matching surface of refractive index $\sqrt{n}$ can be placed over the reflecting surfaces to reduce reflections.

Fig. 94. Fraction of incident power reflected from the surface of an infinite dielectric slab vs. angle of incidence. (*a*) Electric vector perpendicular to the plane of incidence; (*b*) electric vector in the plane of incidence.

87. Artificial-dielectric Lens Antennas.[1] Artificial-dielectric materials can be made up from an array of discrete metal particles or obstacles simulating, as it were, molecular particles supported in a matrix of strong yet lightweight dielectric. The increase in path length (or delay in phase velocity) produced by the metallic particles is due to the increased average polarization of the dielectric medium. The size of the metal particles should be small compared with the wavelength to avoid resonance. (The maximum length parallel to the E field should be less than $\lambda/4$.) The spacing should be less than a wavelength to avoid diffraction effects. The advantages of artificial-dielectric materials over conventional dielectrics include light weight, mechanical strength, and a wide range of refractive indices.

The effective relative dielectric constant and permeability of a number of particles are given on page 20–109.[2] The formulas listed are valid for the particular orienta-

[1] See references 336, 337, 338, 346, 357, and 368.
[2] See reference 338.

Table of Relative Dielectric Constant and Permeability for Various Obstacle Shapes

Obstacle shape	Dielectric constant	Permeability
Thin circular disks	$\epsilon_r = 1 + \frac{2d^3N}{3}$	$\mu_r = 1 - \frac{d^3N}{3}$
Thin ellipses	$\epsilon_r = 1 + \frac{4\pi ab^2k^2N}{3(1-k^2)[F(k)-E(k)]}$, $\epsilon_r = 1 + \frac{4\pi ab^2k^2N}{3[E(k)-(1-k^2)F(k)]}$	$\mu_r = 1 - \frac{4\pi ab^2N}{3E(k)}$
Thin squares	$\epsilon_r = 1 + 1.032\,d^3N$	$\mu_r - 1 - 0.455\,d^3N$
Thin rectangles	$\epsilon_r = 1 + \frac{\pi w^2 lN}{4}$ ($l >> w$)	$\mu_r = 1 - \frac{\pi w^2 lN}{4}$
Thin infinite strips	$\epsilon_r = 1 + \frac{\pi w^2 n}{4}$	$\mu_r = 1 - \frac{\pi w^2 n}{4}$
Circular cylinders	$\epsilon_r = 1 + 2\pi a^2 n$	$\mu_r = 1 - 2\pi a^2 n$ (H perpendicular to axis); $\mu_r = 1 - \pi a^2 n$ (H parallel to axis)
Spheres	$\epsilon_r = 1 + 4\pi a^3N$	$\mu_r = 1 - 2\pi a^3N$
Moderately thick obstacles		$\mu_r = 1 - \tau N$

N is the number of obstacles per unit volume, $k = \sqrt{1-(b/a)^2}$, $F(k)$ and $E(k)$ are complete elliptical integrals, n is the number of obstacles per unit area perpendicular to strips or cylinders, τ is the volume occupied by an obstacle.

tion of the pertinent field vector indicated in the table. The relative permeability of an array of very thin obstacles parallel to the magnetic field is unity. In this table, N is the number of obstacles per unit volume, $k = [1 - (b/a)^2]^{1/2}$, $F(k)$ and $E(k)$ are complete elliptical integrals, n is the number of obstacles per unit area perpendicular to the strips or cylinders, and τ is the volume occupied by an obstacle. The index of refraction is

$$\sqrt{\epsilon_r \mu_r}$$

where ϵ_r = relative dielectric constant
μ_r = relative permeability

Artificial-dielectric materials can also be constructed in the form of an assembly of two or more dielectric materials such as a three-dimensional array of quartz dielectric spheres supported by a foamed dielectric matrix.[1] Or, alternatively, spherical voids, or cylindrical holes, can be arrayed in a matrix of high-dielectric-constant material.[2] Alternate layers of high- and low-dielectric-constant materials have been used to make up artificial dielectric.[3] The relative dielectric constant may be adjusted to any value between those of the component materials by selecting the proper ratio of slab thickness.

Artificial dielectrics can be used to good advantage as matching layers for lenses of homogeneous dielectrics.[4]

88. *E*-plane Metal-plate Lens Antenna.[5] This type of lens is made up of a stack of parallel-plate transmission lines propagating a $TE_{1,0}$ wave. That is, the metallic plates of the transmission line are parallel to the direction of the electric field. The phase velocity for a $TE_{1,0}$ wave in such a line is

$$v = \frac{c}{\sqrt{1 - \left(\frac{\lambda_0}{\lambda_c}\right)^2}} \quad \text{m/sec}$$

where c = free-space velocity (3×10^8 m/sec, approximately)
λ_0 = free-space wavelength
λ_c = cutoff wavelength = $2a$ (a = plate separation)

The index of refraction for this lens is

$$n = \frac{c}{v} = \sqrt{1 - \left(\frac{\lambda_0}{\lambda_c}\right)^2}$$

Note that n is less than 1; hence the electrical paths are reduced by the insertion of a metal-plate lens. Values of n lie between 0 and 0.86. The smallest practical value of n should be used in order to keep the thickness at a minimum. The minimum practical value of n has been found to be about 0.5.

y
O E θ x X
f
FIG. 95. Dimensions of an *E*-plane metal-plate lens antenna.

An *E*-plane metal-plate lens can be designed to have variable thickness and uniform spacing or uniform thickness and variable spacing. The contour of a lens with uniform plate spacing which will focus an incident plane wave is given by (see Fig. 95)

$$R = \frac{(1 - n)f}{1 - n \cos \theta}$$

where n = index of refraction.

[1] See reference 339.
[2] See references 346 and 368.
[3] See reference 338.
[4] See reference 362.
[5] See references 9, 13, 15, and 356.

In rectangular coordinates the equation is

$$\left[\frac{(1+n)x}{f} - n\right]^2 + \left(\frac{1+n}{1-n}\right)\frac{y^2}{f^2} = 1$$

This is the equation of an ellipse. For a point-source primary feed, the lens has a concave ellipsoidal surface and for a line source the lens has a concave cylindrical surface.

In the E plane, focusing is accomplished because of diffraction (Snell's law); however, in the H plane, the waves are constrained to travel parallel to the plates.[1]

A serious disadvantage of this type of lens is its limited bandwidth. If δ is the maximum tolerable path difference in wavelengths between the central and the outermost ray, and t is the thickness, in wavelengths, of the lens plate at the edge, then

$$\text{Band width} = \frac{2n}{1-n^2}\frac{\delta}{t}$$

The thickness of a zone step is (see Fig. 96)

$$z = \frac{\lambda_0}{1-n}$$

where λ_0 = free-space wavelength
n = index of refraction

The contour of the zoned lens is

$$R_K = \frac{(1-n)f_K}{1-n\cos\theta}$$

where $f_K = f + (K-1)z$
f = focal length of unzoned lens
K = number of zones = 1, 2, 3, . . . ; the central zone is counted as the first zone

Fig. 96. Cross section of a zoned E-plane metal-plate lens antenna.

Zoning an E-plane metal-plate lens increases its band width and decreases the size (thickness) of the lens. The band width is given approximately by

$$\text{Band width} \doteq \frac{50n}{1+Kn} \quad \text{per cent}$$

where n = index of refraction at the design frequency.

Practical lenses of this type have band widths of 4 to 5 per cent.

The amplitude $A(\rho)$ at any point in the aperture of a "spherical" lens a distance ρ ($= R\sin\theta$) from the lens axis is related to the geometry of the lens and the amplitude pattern $A(\theta)$ of the primary feed by

$$A(\rho) = \frac{1}{1-n}\sqrt{\frac{(1-n\cos\theta)^3}{\cos\theta - n}}\,A(\theta)$$

For a "cylindrical" lens, the amplitude $A(y)$ at any point y ($= R\sin\theta$) in a cross-sectional plane is given by

$$A(y) = \frac{1-n\cos\theta}{\sqrt{(1-n)(\cos\theta-n)}}\,A'(\theta)$$

where $A'(\theta)$ = field-strength pattern of the line-source feed in the cross-sectional plane as a function of θ.

The directivity is about the same as for an optimum horn of the same aperture.

[1] Constrained-type lens antennas are applicable to wide-angle scanning; see references 342, 359, 373, and 376.

The general problem of reflection from the surfaces of a metal-plate lens is quite complex. Formulas and tables for reflections of plane waves from the edge of an infinite array of parallel equally spaced plates when their edges lie in a plane can be found in the literature.[1] From these rough approximations the magnitude of the reflections from a practical antenna can be determined.
FIG. 97. *H*-plane metal-plate lens antenna.

89. *H*-plane Metal-plate Lens Antenna.[2] The velocity of a wave entering a stack of parallel-plate transmission lines oriented parallel to the direction of the magnetic field is essentially unchanged because the lines will support a *TEM* wave. However, the wave is *constrained* to travel between the plates, so that, once inside, the path length can be increased if the plates are deformed or slanted as shown in Fig. 97. In this type of lens

$$R = \frac{(n-1)f}{n\cos\theta - 1}$$

where n = effective index of refraction = $1/\cos\xi$ $(n > 1)$

ξ = slant angle of the parallel-plate transmission lines

In this lens the index of refraction, $1/\cos\xi$, is independent of frequency and depends only upon the slant angle ξ.

The most critical dimension is the slant length S. Assuming a maximum allowable variation of $\lambda/8$ in the electrical path length, the tolerance on S is

$$\Delta S = \pm 0.06\lambda$$

The chief disadvantage of this type of lens is that the aperture illumination is unsymmetrical in the E plane.

90. Tolerances on Lens Antennas.[3] The tolerances given in the table on page 20-113 are based on a maximum allowable deviation in path length (from all causes) of $\pm\lambda/16$ from a mean value (total variation of $\lambda/8$). A relatively large amount of warping and twisting can be tolerated in a lens antenna compared with a parabolic-reflector antenna, which is an advantage. The lens axis can be tilted with respect to the axis of the feed without serious pattern distortion.

91. Luneberg Lens Antenna.[4] Luneberg showed that, if a dielectric sphere has a variable index of refraction that varies with distance r from the center, as

$$n = \sqrt{2 - (r/a)^2}$$

FIG. 98. The Luneberg lens antenna.

where a = radius of the sphere, then all the energy entering the sphere at a point on the surface is focused into a beam directed diametrically opposite the point. This is shown in Fig. 98. The rays that leave the point source S on the lens surface are focused into parallel rays. A ray leaving the source at an angle θ is radiated from the lens at P so that the radius OP forms the angle θ. Because of symmetry, scanning in three dimensions can be achieved without pattern deterioration by moving the source on the lens surface.

[1] See references 15 and 333.
[2] See reference 358.
[3] See references 9 and 15.
[4] See references 361, 364, and 365.

The variation in the index of refraction is achieved by controlling the density of the dielectric material or by loading a low-dielectric constant material such as a foam with high-dielectric-constant materials.

The amplitude of the field $A(\rho)$ at any point in the projected aperture is related to the feed pattern $A(\theta)$ by

$$A(\rho) = \sqrt{\sec\theta}\, A(\theta) \qquad \text{for } -\frac{\pi}{2} < \theta < \frac{\pi}{2}$$

where θ = angle at which a ray leaves the source.

The restriction on θ is necessary since sec θ approaches infinity as θ approaches $\pm\pi/2$.

Tolerances on Lens and Reflector Antennas*

Type of antenna	Type of tolerance	Amount of tolerance
Parabolic reflector	Surface contour	$\pm 0.03\lambda_0$
Dielectric lens ($n > 1$)	Thickness	$\pm \frac{0.03\lambda_0}{n-1}$
	Index of refraction	$\pm \frac{3\lambda_0}{nt}$ %
Zoned dielectric lens ($n > 1$)	Thickness	± 3 %
	Index of refraction	$\pm \frac{3(n-1)}{n}$ %
E-plane metal-plate lens, unzoned ($n < 1$)	Thickness	$\pm \frac{0.03\lambda_0}{1-n}$
	Plate spacing	$\pm \frac{3n\lambda_0}{(1-n^2)t}$ %
E-plane metal-plate lens, zoned ($n < 1$)	Thickness	± 3 %
	Plate spacing	$\pm \frac{3n}{1+n}$ %

n = index of refraction
t = lens thickness
* See reference 9.

The half-power beam width for a Luneberg lens antenna fed from an open-ended wave guide or small horn is given approximately by

$$\text{Half-power BW} \doteq \frac{30\lambda_0}{a}$$

where a/λ_0 = lens radius in free-space wavelengths.

A two-dimensional Luneberg lens can be constructed from two circular disks forming a parallel-plate line. If the direction of the electric field is normal to the plates, the desired variation in the index of refraction can be achieved by using a slab of variable-index dielectric [$n = \sqrt{2 - (r/a)^2}$] placed between the plates.

For example, a simple method for obtaining a variable dielectric constant as a function of radial distance consists in drilling holes of gradually increasing diameter, as one progresses outward, into a slab of polystyrene. If the direction of the electric field is parallel to the plates, a *TE* wave will be propagated. The desirable index can be obtained by varying the plate separation since in this case, as in the E-plane metal-plate lens,

$$n = \sqrt{1 - (\lambda_0/\lambda_c)^2}$$

where λ_0 = free-space wavelength
λ_c = free-space cutoff wavelength = 2 × plate separation

The half-power beam width in the H plane of a two-dimensional Luneberg lens is given approximately by

$$H\text{-plane half-power BW} \doteq \frac{143}{\sqrt{a/\lambda_0}}$$

where a/λ_0 = lens radius, wavelengths.

92. Microwave Slot Antennas—Slotted-wave-guide Arrays.[1] If a narrow slot is cut into the wall of a wave guide so that its long dimension is in a direction transverse to the current lines, the internal wave-guide field is coupled to space. The degree of coupling depends upon the current density and the projected length of the slot normal to the current lines. This provides a method of excitation.

If the slot is cut so that its long dimension is parallel to the flow of current or is located where the current is zero, there is very little coupling of the internal field to space. Nonradiating slots provide means of entry into the wave guide for measuring the internal fields.

Narrow slots ($W \ll \lambda$) approximately $\lambda/2$ long are used as practical radiating elements on slotted-wave-guide arrays. In this case, the slot field is nearly sinusoidal along its length independent of the method of excitation.

FIG. 99. Parameters and equivalent circuits of slots in rectangular wave guide (reference point for circuit elements is the center of the slot): (*a*) wave-guide dimensions; (*b*) longitudinal slot in broad face, shunt element; (*c*) transverse slot in broad face, series element; (*d*) centered inclined slot in broad face, series elements; (*e*) centered inclined slot in narrow face, shunt element.

The simple equivalent circuits for the most commonly used resonant slots in a rectangular wave guide propagating the dominant $TE_{1,0}$ mode and the corresponding value of loading are given below. If g represents the shunt conductance of a slot normalized to the characteristic admittance of the $TE_{1,0}$-mode line, and r represents the series resistance of a slot normalized to the characteristic impedance, then for a longitudinal slot in the broad face (Fig. 99*b*),

$$g = 2.09 \frac{\lambda_g}{\lambda_0} \frac{a}{b} \cos^2\left(\frac{\pi\lambda_0}{2\lambda_g}\right) \sin^2\left(\frac{\pi x_1}{a}\right)$$

where λ_g = wave-guide wavelength.

The frequency characteristics of longitudinal slots is such that (for slots up to $\lambda/4$ wide) the wider the slot the flatter the response. For a transverse slot in the broad face (Fig. 99*c*), the series resistance is

$$r = 0.523 \left(\frac{\lambda_g}{\lambda_0}\right)^3 \frac{\lambda_0^2}{ab} \cos^2\left(\frac{\pi\lambda_0}{4a}\right) \cos^2\left(\frac{\pi x_1}{a}\right)$$

For a centered inclined slot (Fig. 99*d*), the series resistance is

$$r = 0.131 \left(\frac{\lambda_0}{\lambda_g}\right) \frac{\lambda_0^2}{ab} \left[A(\theta) \sin\theta + \frac{\lambda_g}{2a} B(\theta) \cos\theta\right]^2$$

where
$$A(\theta) = \frac{\cos(\pi\xi/2)}{1-\xi^2} + \frac{\cos(\pi\eta/2)}{1-\eta^2}$$

$$B(\theta) = \frac{\cos(\pi\xi/2)}{1-\xi^2} - \frac{\cos(\pi\eta/2)}{1-\eta^2}$$

[1] See references 15 and 18.

$$\xi = \frac{\lambda_0}{\lambda_g}\cos\theta - \frac{\lambda_0}{2a}\sin\theta$$

$$\eta = \frac{\lambda_0}{\lambda_g}\cos\theta + \frac{\lambda_0}{2a}\sin\theta$$

And for an inclined slot in the narrow face (Fig. 99e), the shunt conductance is

$$g = 0.131\left(\frac{\lambda_g}{\lambda_0}\right)\frac{\lambda_0^4}{a^3b}\left[\frac{\sin\theta\cos\left(\frac{\pi\lambda_0}{2\lambda_g}\sin\theta\right)}{1-\left(\frac{\lambda_0}{\lambda_g}\right)^2\sin^2\theta}\right]^2$$

Where mutual coupling exists between adjacent slots, the shunt admittance or series impedance presented by a slot will, in general, differ from the above values.[1]
FIG. 100. Probe-fed slots on rectangular wave guide. The arrows show lines of current flow.

From a practical point of view dumbbell-shaped slots are used instead of rectangular slots. The perimeter of the slot, for resonance, is approximately equal to a wavelength. This not only decreases slot length but also simplifies machining. A thin sheet of dielectric placed over a slot will also decrease the resonant length.

Arrays of shunt slots are generally constructed by placing them $\lambda_g/2$ apart so they are effectively in parallel and by placing a short circuit at the far end $\lambda_g/4$ from the last slot so that the admittance in parallel with the last slot is zero. Then if there are k elements, the relative conductance of each slot is made equal to $1/k$. If the shunt elements are longitudinal slots cut into the broad wall of the wave-guide feed, the mutual coupling between slots is negligibly small.

The conductance of a longitudinal slot cut into the broad wall can be determined by measuring the input admittance of k slots in parallel because the mutual impedance is negligible. However, when mutual impedances between slots exist, the effective conductance of the slot (in the presence of the other elements) may be found by measuring the additional conductance produced when one slot is added to an array of identical slots. In practice, a number of slots (*e.g.*, 10) are cut and the input admittance determined. The input admittance is then again determined when additional slots are cut in sets of, say, 3. Eventually the total susceptance becomes constant and the conductance linearly proportional to k.

A nonradiating slot can be made to radiate by inserting a suitable probe into the wave guide adjacent to the slot, thereby introducing the necessary asymmetry in the current distribution for excitation. These radiating elements are called *probe-fed*

[1] See reference 344.

slots. The magnitude of the coupling can be controlled by adjusting probe depth, and the direction of field across the slot is determined by the side in which the probe is inserted. That is, the phase can be shifted 180 deg by switching the probe position. Examples are shown in Fig. 100.

Slots have a severe disadvantage at short wavelengths (1 cm), where they become so small that they have insufficient power-handling capacity and the tolerances on dimensions are impractical.

Broadside arrays of slot radiators are obtained by spacing the elements at intervals of $\lambda_g/2$ and changing the phase of successive elements by 180 deg. With shunt slots in the broad wall, the phase reversal is achieved by placing the slots on alternate sides of the center line of the wall, and for shunt-inclined slots on the narrow face, phase reversal is obtained by reversing the inclination of alternate slots. The phase of probe-fed slots is reversed by placing the probe on opposite sides on successive slots, as indicated above.

93. Surface-wave or Traveling-wave Antennas. A number of antennas can be classified as surface-wave or traveling-wave antennas. For example, dielectric-rod ("polyrod") antennas, dielectric-filled tapered-depth antennas, dielectric-sheet antennas, corrugated-surface antennas, helical-beam antennas (operating in the axial radiation mode), to name a few, are "end-fire" types of surface-wave antennas in which the wave velocity v along the antenna is usually less than the free-space velocity c. In this case, most of the energy transported by the wave is carried close to the antenna surface, but it will radiate efficiently if impeded by a discontinuity, such as a change of cross section. In addition to the above, the radiating or *"leaky"-wave-guide antenna* (also called the *channel-guide antenna* and *traveling-wave slot antenna*) and the *"serrated"-wave-guide antenna*[1] are another type of antenna that can be designed to radiate in directions other than in the end-fire direction (c/v less than 1) as well as in the end-fire direction. In general, this type of antenna can be easily scanned by changing the wave velocity along the aperture.

Most of these antennas, with the exception of the polyrod and helical antenna, are flush-mounted, that is, the radiating aperture is flush with the metallic surface in which they are mounted, and hence offer little aerodynamic drag. Most can be designed to give excellent pattern control by adjusting the amplitude and/or phase along the aperture. A variety of polarizations are available depending upon the antenna geometry and mode of excitation. A number of these antennas are filled with a dielectric material and those which are not can be designed with a dielectric sheet covering, which in either case acts as the antenna radome and permits pressurization of the whole system. Like the traveling-wave wire antenna, these antennas have a single feed point and are nonresonant, and so generally they have broad-band impedance characteristics.

FIG. 101. Cross section of the radiation pattern of a traveling-wave slot antenna.

The end-fire pattern is a pencil-type beam. For the flush-mounted antennas the end-fire pencil beam is necessarily modified by the presence of the metallic mounting surface. It appears that, in practice, maximum end-fire directivity is obtained when the wave velocity is such that the Hansen-Woodyard criterion[2] for increased directivity is satisfied, that is,

$$(\beta_s - \beta_0)l = \pi$$

where β_s = phase constant of the surface wave
β_0 = free-space phase constant
l = length of the antenna

[1] See references 354 and 374.
[2] See reference 47.

When radiation occurs in directions other than end-fire, the pattern has the shape of a hollow cone whose axis coincides with the long axis of the antenna, as illustrated in Fig. 101. In this case a good approximation to the radiation pattern of the traveling-wave antenna can be written as the product of the pattern of an element of the aperture and the pattern of a traveling wave which, if the rate of attenuation is small, is of the form $(\sin x)/x$, where x is a function of the polar angle θ, the antenna length, and the relative phase velocity of the traveling-wave field along the antenna. The effect of attenuation on the traveling-wave pattern is to broaden the main lobe, fill in the nulls between the side lobes (which is sometimes desirable), and raise the side-lobe level slightly. If the metallic surface is an infinite ground plane the pattern is independent of the ϕ coordinate; however, in practice it is modified by the size and shape of the surface.

94. Polyrod Antenna.[1] The dielectric-rod or polyrod antenna is a finite length of a tapered dielectric cylinder. If circular in cross section, the dominant mode is a
FIG. 102. Diameter in wavelengths as function of power ratio W_i/W_0, where W_i is the power inside the dielectric wave guide and W_0 is the power outside.

hybrid $TE_{1,1}$ mode, or, if rectangular, the dominant mode is a hybrid $TE_{1,0}$ mode. Neither has a cutoff frequency. Hence, this antenna is a broad-band radiator. However, at low frequencies most of the energy is outside the dielectric, *i.e.*, only loosely coupled to the guide. The ratio of the energy carried inside a circular rod to that outside is shown in Fig. 102 as a function of the diameter in wavelengths. When most of the energy is outside, the phase velocity v is approximately equal to the free-space velocity. When most of the energy is carried inside, the velocity approaches the value it would have if propagating in an unbounded region of the dielectric material. The relative phase velocities as a function of diameter for various dielectric constants ϵ are shown in Fig. 103. The transition region is quite narrow for the higher dielectric constants. If the rod is gradually tapered from a diameter at which most of the energy is inside the dielectric to a diameter at which most of the energy is outside, the effective area of the wave front is large, and this wave front, acting as a secondary source of radiation, produces a pattern similar to a horn. Once most of the energy in the traveling wave is outside the dielectric, the wave velocity is approximately the free-space velocity and the dielectric can be terminated without disturbing the wave.

Because of its properties the dielectric-rod antenna is a broad-band radiator. An example of a practical antenna is shown in Fig. 104.[2]

[1] See reference 13.
[2] See references 9 and 363.
FIG. 103. Ratio of phase velocity along the dielectric wave guide to the velocity of light as a function of diameter in wavelengths.
FIG. 104. A dielectric-rod antenna.

The directivity of the dielectric-rod antenna of length L is given approximately by

$$g \doteq \frac{8L}{\lambda_0}$$

The half-power beam width is given approximately by

$$\text{Half-power BW} \doteq \frac{60}{\sqrt{L/\lambda_0}} \quad \text{deg}$$

where L/λ_0 = antenna length, free-space wavelengths.

The diameter of the circular wave-guide feed must be greater than $0.58\lambda_0/\sqrt{\epsilon_r}$, where ϵ_r is the relative dielectric constant of the dielectric material filling the guide.

95. Dielectric-filled Tapered-depth Antenna.[1] This antenna is equivalent to a flush-mounted polyrod. Basically, it consists of a dielectric-filled wave guide excited

[1] See reference 375.

in the dominant $TE_{1,0}$ mode, as shown in Fig. 105. The cross section of the "radiating" portion of the antenna is tapered in thickness. Typical principal plane patterns for a tapered-depth antenna (with uniform taper) mounted in a finite ground plane are also shown in Fig. 105. In this figure the H plane is the plane of the metallic ground plane; the E plane is perpendicular to the ground plane.

The shape of the E-plane pattern is influenced by the shape and length of the metallic surface beyond the end of the antenna and by radiation from spurious modes
FIG. 105. Tapered-depth end-fire antenna and typical radiation pattern.

set up at the feed end of the aperture due to improper mode conversion at this point. Some pattern control can be obtained by the taper of the dielectric.[1] Very practical antennas, however, have been obtained with uniform tapers. The shape of the H-plane pattern is determined by the aperture width W.

The wave velocity in this antenna is a function of the depth, width, and dielectric constant of the material. The relative velocity ratio c/v for polystyrene dielectric ($\epsilon_r = 2.5$) is shown in Fig. 106 as a function of depth and width.[2] As is true of the dielectric-rod antenna, the wave velocity can vary between the limits $\sqrt{\epsilon_r}$ and 1.0 over a wide frequency range. Hence, the tapered-depth antenna results in an end-fire antenna whose practical band width is limited only by cutoff in the feed section (which

[1] See reference 332.
[2] See reference 375.

can be extended by using a ridged wave guide) and the discontinuity at the beginning of the aperture.

Large-aperture wide-band tapered-depth antennas can be constructed simply as shown in Fig. 107. The flared antenna is effectively a flush-mounted horn. The rectangular aperture is excited by an H-plane sectoral horn with a dielectric lens to correct the phase front. The lens can be constructed as part of the dielectric slab.
FIG. 106. Calculated c/v as a function of wave-guide geometry for polystyrene dielectric.

This principle has been applied in the construction of a tapered circular dielectric-disk antenna to produce a high-gain omnidirectional pattern in the plane of the disk.[1] It consists of a circular dielectric disk, tapered uniformly in thickness from the center to the edge, mounted on a metallic ground plane. The disk is excited from beneath by a dipole—the extended center conductor of a coaxial line. Only the lowest-order (dominant) surface wave mode can exist in the disk as long as its thickness is not greater than $\lambda_0/4\sqrt{\epsilon_r - 1}$, where ϵ_r is the relative dielectric constant. It has been found experimentally that the uniform taper results in the highest gain and lowest side-lobe level.

96. Corrugated-surface Antenna. A corrugated surface similar to the one shown in Fig. 108 will act as a guide for surface waves, with the direction of propagation perpendicular to the length of the corrugations, provided the loading due to the corrugations (slots) is series-inductive.[2] The mode is transverse magnetic (TM), since there is no component of H in the direction of propagation. This occurs when the
FIG. 107. Large-aperture tapered-depth antenna.

depth of slots is less than $\lambda/4$ (plus an integral number of half wavelengths). The phase velocity along the surface is a function of slot depth, varying from free-space velocity at zero depth to zero velocity at a depth of $\lambda/4$. The phase velocity is also a function of surface width w; however, it has been found that the phase velocity is approximately that of a wave on a corrugated surface infinitely wide when w is greater

[1] See reference 352.
[2] See reference 371.

than about 3λ. The attenuation on these surfaces is due chiefly to metal losses and varies between 0.2 and 0.5 db per m.

A corrugated surface can be made to radiate either by matching the impedance of the wave on this surface to free space by means of tapered corrugated sections or by introducing abrupt periodic discontinuities in the surface. Little radiation occurs from the edges of such an antenna. An example is shown in Figs. 109 and 110.[1] The
FIG. 108. Single flat corrugated surface with wave-guide feed.
FIG. 109. Corrugated-surface antenna.

antenna consists of three main parts: the wave-guide feed, generally propagating the dominant $TE_{1,0}$ mode, a *mode transformer* (or *horn launcher*), and the corrugated surface. If the side and top walls of the launcher are gradually flared out over several wavelengths before they are terminated and a tapered corrugated section is inserted in the launcher, a surface wave will be efficiently launched on the corrugated surface with a good match.[2] In general, the radiation pattern consists of a superposition of

[1] See reference 345.
[2] See reference 343.

the radiation from the mouth of the launcher, the corrugated section, and the currents flowing on the finite ground plane beyond the corrugated section. If the contribution of the launcher is to be kept small, its mouth must also be small. This is contrary to the requirements for a good match; hence, the optimum height b (since w will be determined by pattern requirements) should be determined by experiment. b is a
FIG. 110. Simplified antenna system.
FIG. 111. Experimental radiation patterns for two corrugated surfaces 7.33λ long, one having a tooth-to-gap ratio of 3:1 and the other a tooth-to-gap ratio of 1:3, each terminated by a λ/2 ground plane.

function of both β_s and l. It might be possible to adjust the amplitude and phase of the radiation from the launcher to improve the radiation pattern.

If h is the depth of the corrugation, G the gap width, and T the tooth width, the surface dimensions that will permit propagation must satisfy the relation

$$\cot \beta_0 h = \frac{G}{G + T} \frac{1}{\sqrt{(\beta_s/\beta_0)^2 - 1}}$$

where $\beta_0 = 2\pi/\lambda_0$ = free-space phase constant
$\beta_s = 2\pi/\lambda_s$ = phase constant of the surface wave
$\beta_s/\beta_0 = c/v$

This relation holds if the number of corrugations per wavelength is large (greater than 19 per wavelength) and the tooth width/gap width ratio is small. The latter condition holds strictly when the corrugated surface is being used as a transmission line because it has been found in practice that there was no significant difference in the radiation patterns for surfaces with tooth width/gap width ratios of 3:1, 1:1, and 1:3. An example of the type of radiation pattern (E plane) obtained from the corrugated-surface antenna and the effect of tooth width is shown in Fig. 111 ($\theta = 0$ deg corresponds to the direction of the long axis of the surface in the direction of propagation). The value of $\beta_s/\beta_0 = c/v$ in this relation is generally chosen to satisfy the Hansen-Woodyard relation for optimum end-fire directivity, *i.e.*, $(\beta_s - \beta_0)l = \pi$.

The width of the surface is determined by the required H-plane (horizontal) beam width. The beam width and tilt angle (angle above the ground plane) of the main beam are functions of the length of the corrugated section and the length and shape of the ground plane beyond it.

To effect a match to free space from the end of the corrugated surface, a tapered section f a few wavelengths long is inserted between the end of the corrugated section and the ground plane.

97. Leaky-wave-guide or Traveling-wave-slot Antenna.[1] The leaky-wave-guide or traveling-wave-slot antenna is similar to the traveling-wave wire antenna, but it is far more versatile because the phase velocity and the rate of radiation of the fields in the antenna, and hence its pattern, can be controlled by the geometry of the antenna. (This type differs from those previously mentioned primarily in that $c/v \leq 1$.) In general, this antenna consists of either a long slot cut so that it is parallel to the long axis of the guide or an array of closely spaced nonresonant slots cut into one wall of a wave guide. The guided waves are characterized by a complex propagation constant since energy in the waves escapes from the wave guide.

There are four typical field configurations associated with traveling-wave-slot antennas which are excited by a uniform wave guide whose axis is parallel to the length of the slot. These are: (1) the conventional transverse electric (no tangential E parallel to slot length); (2) transverse magnetic (no tangential H parallel to slot length); (3) a hybrid with a negligible transverse E component; and (4) a hybrid with a negligible normal H component.

Any of these configurations can be excited by proper positioning of a long slot in the wall of a uniform wave guide of rectangular or circular cross section. To obtain the transverse electric excitation a narrow slot must be placed where the current in the wall of the wave guide is perpendicular to the slot. The transverse magnetic excitation is obtained from an air-filled wave guide having a wide slot (about $\lambda/2$) positioned so that the current flow is parallel to the slot length. The hybrid excitation (3) is obtained under the same conditions as the TM excitation, except that the wave guide is filled with dielectric having a dielectric constant of 2.0 or greater. The hybrid excitation (4) is obtained from a wave guide partly filled with dielectric (such as polystyrene) which is excited in the lowest-order (hybrid) wave-guide mode. (This mode also exists in the tapered-depth antenna.)

The propagation constants for TE and TM types of traveling-wave-slot antennas are shown in Figs. 112 to 115 in the form of the velocity ratio c/v and attenuation constant α in nepers per wavelength, where c is the free-space velocity and v is the phase velocity along the slot aperture.[2]

The radiation pattern has the shape of a hollow cone with its axis coincident with the slot axis (see Fig. 101). For an antenna with a uniform cross section (*i.e.*, c/v is a constant, and the strength of the aperture field decays exponentially), the radiation pattern, assuming the aperture is in an infinite ground plane, is given by

$$|E(\theta,\phi)| = k|f(\theta,\phi)| \left\{ \frac{1 - 2e^{-\alpha l} \cos [\beta_0 l(c/v - \cos\theta)] + e^{-2\alpha l}}{(c/v - \cos\theta)^2 + (\alpha/\beta_0)^2} \right\}^{1/2}$$

[1] See references 240, 348, 349, and 370.

FIG. 112. Measured velocity ratios c/v of an air-filled *TE* traveling-wave-slot antenna.
FIG. 113. Attenuation constants of an air-filled *TE* traveling-wave-slot antenna.
FIG. 114. Measured velocity ratios of an air-filled *TM* traveling-wave-slot antenna of square cross section with $TM_{1,1}$ excitation.
FIG. 115. Attenuation constants of an air-filled *TM* traveling-wave-slot antenna of square cross section with $TM_{1,1}$ excitation.

where $f(\theta,\phi)$ = the pattern of a differential element of the aperture (= $\sin\theta$ for *TE* types, for example) .

α = attenuation constant, nepers per m

β_0 = free-space phase constant, radians/m

l = length of aperture, m

k = constant

If α is small, then to a good approximation the direction of maximum radiation θ_m is given by

$$\theta_m = \cos^{-1} (c/v)$$

This also neglects the influence of the pattern of the differential element, but if l is large ($>5\lambda$), this is still a good approximation.

Beam shaping can be accomplished with this type of antenna by using a slot whose width W varies with distance along the slot to give the desired amplitude distribution. That is, the rate of attenuation (radiation) along the antenna can be controlled by the aperture width. If this variation in W also results in an undesired change in the phase velocity, the depth or cross section can be modified to compensate for it.

An approximation to the desired variation in the attenuation constant along the slot to obtain an amplitude distribution represented by the function A is

$$\alpha(z) = \frac{1}{2} \frac{A^2}{\int_z^l A^2 \, dz + \frac{P(l)}{P(0) - P(l)} \int_0^l A^2 \, dz}$$

where $P(0)$ = input power at $z = 0$
$P(l)$ = power left over at $z = l$
l = length of slot aperture

It has been found from experience that the exact array-design procedure (described in Sec. 29) must be employed in designing arrays of traveling-wave antennas when the element spacing is less than about 2λ.

The mutual impedance between traveling-wave-slot antennas may be analyzed by picturing the traveling-wave slot as a directional coupler. When two such slots are placed along parallel lines, the field induced in one due to energization of the other will consist primarily of a wave traveling in the same direction as the wave in the slot which is energized directly. This wave will be reflected at the end of the parasitic slot and will travel back to its input terminals. However, it is attenuated by radiation as it travels along the slot so that the amount available at the input terminals of the parasitic slot is very small. If the slots are long enough to be good directional antennas, the coupling between adjacent input terminals is very small. In practice it has proved to be negligible.

The magnitude of the mutual impedance is quite different for the *TE*, *TM*, or hybrid slots. For example, the equivalent magnetic dipoles associated with parallel slots are broadside to broadside for *TE* operation, whereas they are end to end for hybrid operation (3) (no transverse *E*). Consequently the mutual-impedance effects associated with hybrid operation (3) are much less than with *TE* operation.

CHAPTER 21

BROADCASTING

By Carl G. Dietsch[1]

1. Principal Elements of Broadcasting System. All the equipment of a broadcasting system extending from the microphone to the radiating antenna of the radio transmitting station will be considered as part of the system. A general circuit layout of typical facilities of the kind used in the larger broadcasting centers for supplying a network of stations with program service is represented by the simplified diagram, Fig. 1. Equipment of a single studio is represented; that of other studios of the usual group would be similar and would be at the point marked on the program bus. Inasmuch as many programs, such as the broadcasting of special events, originate at remote points, in most cases a great distance from the studio, the layout of the facilities for remote pickups, sometimes termed "nemo" programs, has been included to illustrate the use of telephone lines as well as point-to-point radiotelephone communication to complete the circuits necessary.

A list of the essential elements of the system is as follows:

1. Microphones
   - *a.* Studio
   - *b.* Remote pickups
2. Apparatus for controlling and conveying microphone output
   - *a.* Studio control booth
     - (1) Preamplifiers
     - (2) Microphone mixers
     - (3) Studio amplifier
     - (4) Volume control or faders
     - (5) Volume indicator
     - (6) Monitoring speaker
   - *b.* Remote pickups
     - (1) Preamplifiers
     - (2) Volume controls or faders
     - (3) Volume indicator
     - (4) Monitoring equipment
     - (5) Radiotelephone or wire-line facilities for intercommunication
3. Master control-room apparatus
   - *a.* Volume controls
   - *b.* Studio amplifiers
   - *c.* Relays and switching apparatus
   - *d.* Network channel amplifiers
   - *e.* Volume indicator
   - *f.* Monitoring facilities
4. Telephone-line facilities to local radio transmitting stations and to distant radio transmitters connected to networks
5. Radio transmitter
   - *a.* Limiting amplifier
   - *b.* Volume controls
   - *c.* Volume indicator
   - *d.* Radio transmitter
   - *e.* Monitoring equipment
     - (1) Monitoring rectifier and speaker
     - (2) Modulation-percentage indicator
     - (3) Carrier-frequency monitor
   - *f.* Antenna

[1] Engineering Department, RCA Communications, Inc.

2. A-f Range. Perfect reproduction of a sound transmitted through an electro-acoustic system requires that the system pass all the audible frequencies of the sound in their relative intensities. Under these conditions of reproduction, the listener would be conveyed acoustically from his loud-speaker to a point near the sound source

FIG. 1. Schematic diagram of typical broadcast transmitting system.

except that the absolute sound level might be different from that experienced at the point of origin.

A correlated acoustic chart of the frequency range of various musical instruments within the orchestral range and the different voices which constitute the vocal range is shown in Fig. 2. The shaded keys are not included on a standard piano keyboard. The extreme organ range not shown on the chart is from 16 to 16,384 cps physical pitch. The extreme frequency-transmission ranges necessary to produce perfect

FIG. 2. Correlated acoustic chart showing the scientific or philosophical scale generally used by physicists and the international equally tempered scale based on $A = 435$ complete vibrations per second. The current orchestra or symphony scale based on $A = 440$ is generally used by musicians.

naturalness of speech and orchestral music are shown in Fig. 3. These ranges extend considerably above those of Fig. 2 because they include overtones and noise accompaniment additional to the fundamental tones. Research[1] indicates that for perfect reproduction of speech and music a frequency range between 30 and 15,000 cps is

[1] Snow, W. B., *J. Acoust. Soc. Am.*, July, 1931, p. 61.

desirable in order that the average ear may appreciate fully all the frequencies produced by the sound sources.

The curves shown in Fig. 4 are an indication of the relative qualities of reproduced orchestral music the frequency range of which was limited by electrical filters. It is apparent that, where a transmission system has a limited frequency range, such as
FIG. 3. Frequency range required for the reproduction of musical instruments, voice, and noise without noticeable distortion.

that which exists in broadcasting techniques, acceptable reproduction may be secured within a band width of between 30 and 9,000 cps.

The engineering and economic limitations of the frequency range used for standard broadcasting lie in restrictions on the use of the upper audio frequencies due largely to a limited band width of the modulation spectrum contained between the presently assigned carrier frequencies of 10-kc separation[1] for standard broadcasting in the spectrum between 550 and 1,600 kc.

[1] Eckersley, P. P., Minimum Frequency Separation, *Proc. IRE*, February, 1933, p. 195.
FIG. 4. Quality of orchestra music as a function of cutoff frequency.

Note	Cps	Organ pipe	Remarks
C_{10}	33,488	....	Beyond limit of audibility for average person
C_9	16,744		
	15,000	....	Considered ideal upper limit for perfect transmission of speech and music
	10,000	....	Considered as upper limit for high-quality transmission of speech and music
	9,000	....	Considered as satisfactory upper limit for high-quality transmission of speech and music
C_8	8,372	¾ in.	Highest note on fifteenth stop
C_7	4,186	....	Highest note of pianoforte
G_6	3,136		
E_8	2,673.2	....	Approximate resonant frequency of ear cavity
	3,000	....	Considered as satisfactory upper limit for transmission of speech for ordinary communication
C_6	2,093		
	2,000	....	Maximum sensitivity of human ear
	1,500	....	Mean speech frequency from articulation standpoint
	1,000	....	Representative frequency of telephone currents
E_4	659.3		
A_3	440	....	Orchestral tuning (see note below)
C_3	261.6		
C_2	130.8		
	100	....	Considered as satisfactory lower limit of good transmission of speech and music
E_2	82.4		
C_1	65.4	8 ft	Lowest note of cello
B_0	61.7		
C_0	32.7	16 ft	Lowest note of average church organ
	30	....	Considered ideal lower limit for perfect transmission of speech and music
A	27.5	....	Lowest note of pianoforte
G	24.5		
C	16.35	....	Lowest audible sound. Longest pipe of largest organ

Notes of the "gamut"	C	D	E	F	G	A	B	C
Vibration frequencies proportional to	1	$\frac{9}{8}$	$\frac{5}{4}$	$\frac{4}{3}$	$\frac{3}{2}$	$\frac{5}{3}$	$\frac{15}{8}$	2
Intervals between successive notes	$\frac{9}{8}$	$\frac{10}{9}$	$\frac{16}{15}$	$\frac{9}{8}$	$\frac{10}{9}$	$\frac{9}{8}$	$\frac{16}{15}$	

FIG. 5. Frequencies to be transmitted on a high-quality system. NOTE: Nearest note is indicated. Scale A = 440 cps based on middle C_1 (symphony pitch) = 261.6 cps.

An overlapping of the modulation frequencies of a "wanted" station by those of an "unwanted" station of 10,000-cps separation restricts the range of frequencies to a broadcast listener usually considerably below that passed by the broadcasting system itself. The high quality of programs available from broadcasting facilities which have an over-all uniform frequency response from the microphone to the antenna within 2 db from 30 to 9,000 cps and above cannot be appreciated by the average listener because of limitations in the average receiver frequency response and restrictions in the present standard broadcast band due to the 10-kc channel separation. Adjacent channel interference in the form of cross talk or "monkey chatter" prevents the satisfactory reception of the higher audio frequencies.

This limitation is not apparent in the case of f-m broadcasting, since the channels are assigned sufficiently far apart to permit transmission and reception of audio frequencies up to 15,000 cps. This is obviously an advantage over standard broadcasting in that the entire audible frequency range may be satisfactorily transmitted and reproduced at the receiver.

Table 1. Peak Power of Musical Instruments

Instrument	Peak Power, Watts
Heavy orchestra	70
Large bass drum	25
Pipe organ	13
Snare drum	12
Cymbals	10
Trombone	6
Piano	0.4
Trumpet	0.3
Bass saxophone	0.3
Bass tuba	0.2
Bass viol	0.16
Piccolo	0.08
Flute	0.06
Clarinet	0.05
French horn	0.05
Triangle	0.05

3. Volume Range. Table 1 gives the peak power of various musical instruments playing triple forte. A violin playing very softly has an output of about 4 mw, whereas that of a full orchestra has a peak value of 70 watts. The intensity range of the sound sources in this case is about 43 db. Owing to limitations in broadcasting circuits, background noise, and the modulation capabilities of the transmitter, this volume range must be in most cases compressed within the limits which can be handled by the wire lines and their associated equipment, as well as the transmitter where serious amplitude distortion results if modulation peaks, except those of extremely short time duration, exceed the modulation capabilities of the transmitter.

STANDARD REFERENCE LEVELS

4. Vu and Decibels. The electrical signal level of an audio signal passing through each particular circuit of the broadcasting system, including the studio equipment, wire-line facilities, and the broadcasting station, must at all times be carefully adjusted. The adjustment must be such that the transmitter program signals will remain within the limits which every part of the system can transmit without objectionable distortion due to overloading or from interference caused by noise, such as the interference produced by cross talk, induction, rectifier ripple, etc., inherent in equipment as well as associated wire lines. A convenient and consistently accurate method of measuring the amplitude of the signals is required, as well as a reference level common to the entire system. On this reference level, termed the *zero reference point* or zero vu (volume units), is based the amplitude of the program waves throughout the system. The zero reference level of 1 mw is expressed as zero *dbm* for a single sine-wave frequency. It also serves as a reference level from which the amplitude of interference or noise may be measured in terms of a sine wave.
FIG. 6. Decibels, watts, and per cent volts; zero level is 1 mw across 600 ohms.

For broadcasting technique together with the interconnecting wire lines between studios and broadcasting stations there has been established a standard energy reference level of 1 mw. For the standard line impedance or pure resistance of 600 ohms at the terminals of a piece of apparatus in the system the zero reference level in vu would correspond to $\sqrt{0.6}$ rms volt of 1,000-cps sine-wave electrical energy as measured by a standard a-c voltmeter across the terminals (see also Chap. 13).

Since program signals have very complex wave shapes and because peaks of these complex waves are liable to cause overloading, a standard volume indicator[1] has

[1] Chinn, H. A., D. K. Gannett, and R. M. Morris, A New Standard Volume Indicator and Reference Level, *Proc. IRE*, January, 1940.

been adopted for the purpose of measuring program levels at all parts of a broadcasting system so that the correct signal level can be maintained without objectionable overloading. This instrument (see Sec. 21) is calibrated to read vu on a logarithmic scale. It has electrical characteristics approximately equivalent to those of an rms instrument. For signals having sinusoidal wave shape, the vu readings on this instrument should follow the decibel-voltage curve shown in Fig. 6. However, since the instrument is designed and used for measurement of complex program waves, the vu level of a particular program wave is as indicated by this standard volume indicator because of its particular characteristics. The term vu is therefore associated with the reading of this meter whereas the term decibel follows steady-state conditions and mathematical laws.

FIG. 7. Directional characteristics of 44BX velocity microphone.

Simultaneously with the establishment of the reference level of 1 mw, the former 0-db levels of 6, 10, 12½ mw, etc., were abandoned in 1939 and the value for standard apparatus and telephone-line termination impedances for broadcasting was changed to the present standard of 600 ohms.

AUDIO FACILITIES

5. Microphone Requirements. By means of the microphone, acoustic energy of sound waves is converted into electric energy, the wave shape of the latter conforming to that of the sound waves. The principal requirements of a microphone which will produce high-quality conversion are as follows: a relatively high sensitivity with respect to its inherent noise level, a uniform wave response over the frequency range desired, a substantially uniform frequency response over the angles included by its directivity characteristic, and mechanical and electrical ruggedness.

With some reservation, one may say that all forms of acoustoelectric transducers require the introduction of an obstacle into the path of the sound waves. To be effective, either the active element of a microphone must partake of or otherwise influence the motion of the air particles, or it must respond in some way to the pressure variations on its surface. Some portion of the instrument such as the outside case, regarded as a rigid obstacle, must reflect some of the incident wave energy, whereas the element which responds to vibration from the sound waves must reradiate some of the energy exciting it. An instrument of high sensitivity and efficiency must, therefore, absorb a considerable proportion of the sound energy reaching it and convert it into electric energy. Faithful reproduction, therefore, is dependent upon the physical size and shape of a microphone. These features enter into the distortion of the true sound field, as well as the characteristics of the elements used to convert the sound into electric energy with a minimum of wave distortion.

Inasmuch as the quality of reproduction of speech and music is dependent upon the acoustic properties of the room[1] containing the sound sources and the placement of the microphone with respect to them, satisfactory results using even the best instruments require a knowledge of the technique of microphone placement.

[1] Hanson, O. B., and R. M. Morris, Design and Construction of Broadcast Studios, *Proc. IRE*, **19**, January, 1931.

6. Velocity Microphone. This instrument gets its name from the movement of a metallic ribbon under the motion of air particles impinging upon it, thus setting up by electromagnetic induction an emf corresponding to the amplitude variations of an incident sound wave.

The commercial form of the RCA type 44BX[1] consists of a thin metallic ribbon suspended between the poles of powerful permanent magnets with the ribbon length perpendicular to, and its width in the plane of, the magnetic lines of force. It is moved from its position of equilibrium by the difference of pressure between its two sides. This pressure difference between the front and back of the ribbon is the same as that produced in a sound field between two points in space separated by this distance. The pressure difference between the front and back of the ribbon is proportional to frequency. Since the acoustic impedance of the system is also proportional to frequency
FIG. 8. Open-circuit frequency response of 44BX microphone.

and since velocity in a mechanical system is the ratio of the pressure to the acoustic impedance, the velocity of the ribbon is independent of frequency.

With a ribbon constructed to have a natural period below the audible range, the frequency response is free from severe irregularities prominent in some pressure-operated types because of cavity and diaphragm resonance and from pressure-doubling effects produced at the higher frequencies. The ribbon is made light enough so that its motion will conform with the motion of air particles even at very high frequencies, with a result that the response of the velocity microphone is uniform over a wide range of frequencies.

The velocity-type microphone is markedly directional. With a plane-progressive wave the response in front and back of the instrument varies with the cosine of the angle between the direction of the sound wave and the normal to the ribbon. Since these directional properties are practically independent of frequency, they become useful in discriminating against undesired sounds and for obtaining a desired relation between the sounds from different sources and from reverberant sound in a studio. Its response[2] to reverberant or reflected sound is one-third that of a nondirective system, with the result that it can be used at a distance from a sound source of 1.7 times the distance of a nondirective type and still give the same results with respect to undesired reverberant sounds.

Because of the directional properties of the instrument, its sensitivity is at a maximum in directions in front and back perpendicular to the plane of the ribbon. With an input sound pressure of 10 dynes per sq cm the unit will normally deliver an effective output level of −54 dbm based on a reference level of 0.001 watt.

7. Moving-coil or Dynamic Microphone. This type of instrument (similar to Altec Lansing 633C) utilizes a light movable coil contained in a magnetic field to produce an emf which conforms with the sound waves impinging upon the dome-shaped diaphragm.

[1] Olson, H. F., *J. Soc. Motion Picture Engrs.*, **16**, 695, 1931; *J. Acoust. Soc. Am.*, **3**, 56, 1931.
[2] Olson, *loc. cit.*

The assembly is composed of a coil of fine aluminum ribbon edgewise wound and attached rigidly to a duralumin diaphragm of low mechanical stiffness which supports the coil in a radial magnetic field of a permanent magnet made from high-grade magnet steel. The diaphragm has a rigid dome-shaped center and a tangentially corrugated annulus. It has a high area/stiffness ratio. The diaphragm is cemented to a raised annulus on the outer pole piece. The outer and inner pole pieces are of soft iron and are welded directly to the magnet. The diaphragm is damped by an acoustic resistance which is supported below the coil by a brass ring, which in turn is held in place by rubber gaskets.

When the diaphragm vibrates in response to the sound waves impinging upon its surface, the coil vibrates in a like manner and cuts the magnetic lines of force. The emf generated in the coil is substantially proportional to the sound vibrations which cause the diaphragm movement.

The shape of the microphone housing and its size are such that the housing fits closely over the diaphragm and thus produces very little more diffractive effect than the diaphragm itself. To prevent resonance within the case an acoustic resistance baffle is provided to divide the space in two parts. A tube with its outlet at the back of the housing serves the double purpose of equalizing the inside and atmospheric pressures and of increasing the response of the instrument at low frequencies.

This microphone was designed to provide a uniform frequency response in all directions and has been termed a *nondirectional microphone*. For this reason the small cylindrical shape was selected as well as the method of mounting the diaphragm in a horizontal plane. A protective grid is provided over the diaphragm to control the resonance of the cavity in front of the diaphragm.

Wave-response calibration curves of this type of instrument indicate that the frequency characteristics are influenced to some extent at the higher frequencies by the angle of incidence from which the sound waves approach the diaphragm. Since the diaphragm is mounted horizontally, the instrument is entirely nondirectional with respect to the vertical axis.

The effective output level of the 633C microphone is −55 dbm as based on a sound input pressure of 10 dynes per sq cm and a reference level of 0.001 watt, and the frequency response is quite uniform over the range of 35 to 12,000 cps.

FIG. 9. Simplified cross-section view of the cardioid directional microphone.

8. Unidirectional Ribbon Microphone. In certain forms of studio technique it is desirable to eliminate the pickup of unwanted sound in the rear of the microphone, such as audience noise, room echo, etc. Here the unidirectional microphone is very useful.

The Altec Lansing 639A cardioid directional microphone utilizes a ribbon element of special design in combination with a compact pressure-type nondirectional element to secure a field response having a directional characteristic similar to a cardioid.

The pressure element is of the dynamic type having a dome-shaped diaphragm and constructed in some respects similarly to the dynamic microphone previously described. Commercial instruments of this general type have switches which enable the directional characteristics to be changed at will. The frequency-response characteristic of the type 639A microphone is quite satisfactory over a range of 40 to 10,000

cps. The output impedance is 30/50 ohms. It will deliver an effective output level of approximately −56 dbm as based on a sound input pressure of 10 dynes per sq cm and a reference level of 0.001 watt.

9. Polydirectional Microphone. The RCA type 77DX microphone combines the features of the velocity and pressure microphones to provide polydirectional characteristics by means of simple internal adjustments. This microphone is a high-fidelity instrument containing a simple ribbon suspended in an air gap formed by the pole pieces of a permanent magnet. The ribbon is divided into two individual sections, one of which is pressure-operated and the other velocity-operated.

The field response of the pressure-operated section is very nearly uniform in all directions and may be expressed as $E = E_0$, whereas the response of the velocity section is bidirectional and is equivalent to $E = E_0 \cos \theta$. Since the sensitivity of the nondirectional pressure section is made to equal the greatest sensitivity of the bidirectional or velocity section, the combined polar field-response characteristic of the two is equivalent to $E = E_0(1 + \cos \theta)$. In three-dimensional space, this is very nearly equivalent to a cardioid of revolution. The point of maximum sensitivity is directly to the front of the instrument, while directly to the rear the sensitivity approaches zero.

FIG. 10. Elements of the unidirectional ribbon microphone.

A uniform frequency response in all directions for the pressure-operated ribbon section is approached by allowing the operating face to be freely accessible to the atmosphere while the other side is terminated in an acoustic impedance very nearly equivalent to that of a very long pipe. Since a long pipe is too cumbersome for practical purposes, a short pipe of correct cross section, provided in coiled form and loaded through its length with absorbing material, such as tufts of felt, exhibits a suitable acoustic resistance over a frequency range covering all but the lowest frequencies.

The operating properties of the velocity-actuated ribbon section are the same as were described previously for the bidirectional velocity microphone. The ribbon is driven from its equilibrium position by a difference of pressure between the two sides, the pressure difference being due to the difference in phase between the two sides. The vibration of the ribbon caused by the sound waves impinging upon it causes an induced emf to be generated in the ribbon. The directional characteristics of the ribbon section are practically independent of frequency.

The polydirectional microphone differs from the conventional velocity microphone in that one entire side of the microphone ribbon is covered by a connector tube which is coupled to a damped pipe or labyrinth. Behind the ribbon in the connector tube an aperture in the form of an adjustable shutter is provided to permit various areas of opening between the ribbon and outside air. When the aperture is completely closed by the shutter, the microphone operates in the same manner as a pressure type. Under these conditions it has nondirectional characteristics. When the shutter is in the wide-open position, the ribbon is open to the air in front as well as to the rear and the microphone operates like the velocity type already mentioned. Under these conditions it has bidirectional characteristics. A common cardioid or unidirectional pattern is secured by an intermediate position of opening of the shutter. Directional patterns of the three types mentioned above are shown in Fig. 11. These are secured by settings of an adjustment screw on the rear of the microphone housing to marked positions.

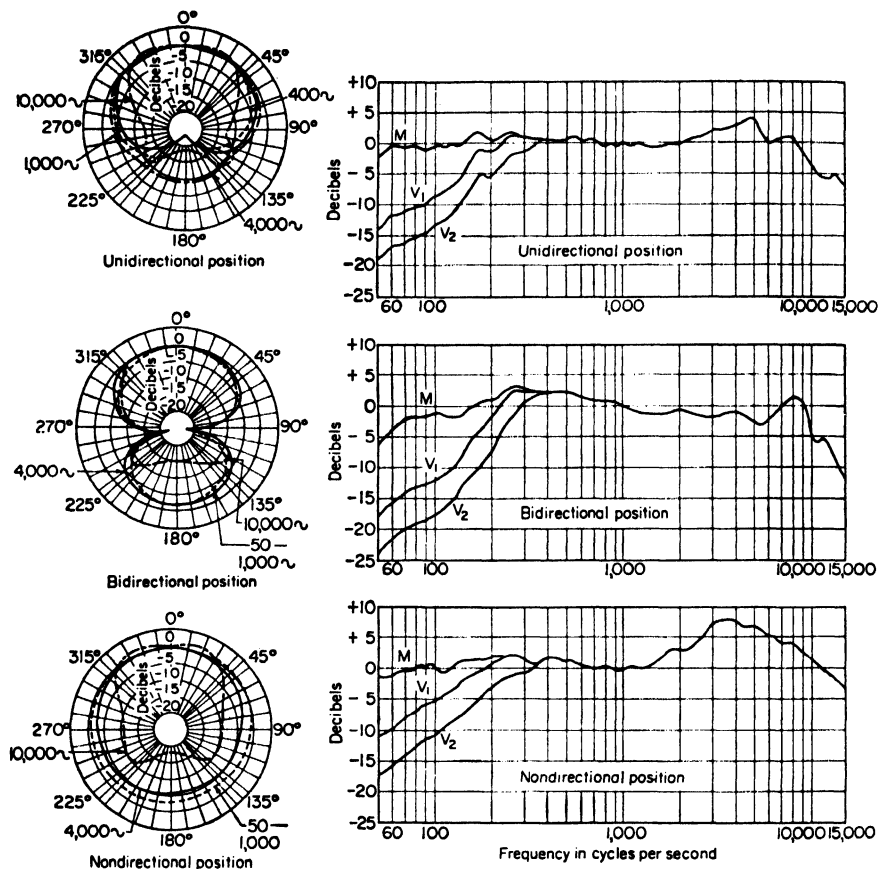
To provide different amounts of l-f attenuation of the microphone response char-


FIG. 11. Directional patterns and frequency response of 77DX polydirectional microphone.

acteristics under conditions of different directional settings of the shutter, a reactor is provided to shunt the output of the microphone transformer. A switch is provided within the lower shell to cut the reactor into the circuit as indicated by Fig. 12.
FIG. 12. Connections for type 77D microphone.

This microphone, by virtue of the polydirectional characteristics, provides a means of controlling the ratio of directional to reverberant sound as well as reducing unwanted sound such as audience noise. There are numerous applications of various directional patterns and the different response characteristics of this microphone to provide usefulness under various operating conditions. It is possible to secure any type of limaçon[1] directional characteristic by means of the shutter adjustment. Because of the variable directional characteristics with respect to the sound source at a point directly in front of it, the sensitivity is dependent upon

[1] Olson, H. F., Polydirectional Microphone, *Proc. IRE*, February, 1944, p. 77.

the directional setting. For bidirectional operation, the sensitivity is approximately equal to that of the velocity microphone previously described.

10. Crystal Microphone. This microphone utilizes the piezoelectric phenomenon produced in plates cut from piezoactive crystals. Thin plates cut from Rochelle-salt crystals are used almost entirely for the elements of crystal microphones. In comparison to other crystalline piezoelectric materials, such as quartz, Rochelle salt exhibits greater sensitivity for this purpose and it responds quite readily to mechanical vibrations.

Crystal microphones may be classified under two individual groups: (1) those utilizing multiple sound cells in free space and (2) those utilizing Bimorph[1] crystal elements each excited mechanically by an associated diaphragm. In the first of these types utilizing the Brush Development Company assembly, termed the *sound cell*, the elements are plates having dimensions 3/8 by 3/8 by 0.30 in. cut from Rochelle-salt crystals along axes in such a manner that their inherent characteristics tend to cause elongation or contraction when they are subject to an electric field provided by foil electrodes.

By cementing together two such piezoactive plates which have tendencies to act in opposition to each other when a voltage is applied, an assembly is produced with a motion analogous to the mechanical motion of bending a bimetallic thermostatic strip acted upon by variation of temperature. The assembly consists of two plate combinations mentioned above, separated by an airspace and held in position by a suitable mounting.

The cell is covered over with a membrane which serves as a pressure seal and protects the crystals from the outside atmosphere. When the cell is placed in a sound field, pressure acting normal to the outer surfaces of the plates tends to cause bending, with a result that an emf is generated between the foil electrodes. The two plate combinations are connected in parallel. The wave form of this emf conforms with that of sound waves. Because of the small physical dimensions of the plates, the frequency of mechanical resonance of the system is rather high, with the result that frequency response is quite uniform over a wide frequency range. Some models are quite uniformly sensitive up to 15,000 cps.

Commercial models contain series and series-parallel groups of these sound cells ranging from 2 to as many as 24. The sensitivity of a single sound cell is approximately −90 db, while a multicell microphone has a sensitivity as great as −68 db based on a zero reference level of 0.001 watt with a sound input pressure of 10 dynes per sq cm.

The output impedance (which is purely capacitative) of these instruments is quite high. This sometimes requires them to be operated directly into the grid of an amplifier tube having a grid leak of about 5 megohms. The small physical dimensions of a single cell make it practically nondirective. This property is also characteristic of multicell units. Figure 13 shows an *RC* amplifier suitable for use with such a microphone.

Fig. 13. Schematic diagram of amplifier for crystal microphone.

The diaphragm type utilizes a hermetically sealed Bimorph crystal supported at three points within the microphone housing. Projecting to the center of the specially treated fiber diaphragm is a small drive pin. This engages the remaining corner of the Bimorph crystal. Inasmuch as the Bimorph crystal is highly sensitive in converting fluctuating mechanical stresses, such as those caused by bending, into corresponding electrical fluctuations, the fluctuations in pressure created by the sound waves impinging upon the microphone diaphragm result in corresponding voltage fluctuations produced across the terminal ends of the Bimorph crystal plates.

[1] Brush Development Co. trade name.

Similar to most pressure-operated microphones, this instrument is semidirective. However, the smallness of the instrument assists in securing a rather uniform frequency response with direction. By placing the diaphragm facing the ceiling of the room, the instrument is essentially nondirectional in a plane through the diaphragm and parallel with the ceiling.

The output impedance of the crystal element is approximately 250,000 ohms. This does not permit long cables to be employed when high impedance connections are used. By means of a high-quality matching transformer this microphone can be satisfactorily operated into circuits exhibiting 50, 200, or 600 ohms impedance. The frequency response of this instrument is substantially flat from 100 to 5,000 cps. It has a variable control to allow manual adjustment of frequency-response characteristic while in operation. With an input sound pressure of 10 dynes per sq cm applied to the diaphragm the average crystal microphone of this type has an output level of approximately −48 dbm based on a zero reference level of 0.001 watt.

The crystal microphone shunted across the input resistor of the amplifier tube attenuates the higher frequencies of background noise such as those caused by thermal agitation. The properties of the crystals themselves are such that they are liable to damage, such as a change of frequency characteristics and output if the instrument is subjected to temperatures in excess of 120 to 125°F, particularly for periods of several hours.

11. Condenser Microphones. The condenser microphone utilizes the principle of mechanical variation of thickness of the air dielectric of a charged electrostatic capacitor as a medium to change acoustic energy into electrical energy of corresponding wave shapes. One form of this microphone consists essentially of an electric capacitor formed by a thin, tightly stretched duralumin diaphragm spaced approximately 0.002 in. and insulated from a flat brass disk called the *back plate.*

A polarizing potential difference is applied between the electrodes formed by the diaphragm and the back plate. The varying pressure upon the very thin diaphragm by the sound waves causes the electrostatic capacitance to vary by an amount in the order of 0.01 per cent of its normal value of 200 $\mu\mu$f.

The microphone has an aluminum alloy diaphragm 0.001 in. in thickness. The edges are clamped between threaded rings, the requisite stiffness being obtained by advancing the stretching ring until the desired resonant frequency is obtained. The space between the diaphragm and the back plate is hermetically sealed to prevent dust and moisture from entering and resulting in noise. The thin rubber auxiliary diaphragm, together with a small air-vent hole in the center of the back plate, is provided as an equalizing system for changes in atmospheric pressure.

On account of its inherent high-impedance characteristics, it is usual to incorporate an amplifier in the microphone housing to reduce to a minimum the length of the lead and the corresponding shunting capacitance between microphone and associated amplifier grid. A d-c polarizing voltage in excess of 180 volts has been used on some models.

Developments upon the early Wente[1] models by using duralumin as a substitute for steel as diaphragm material brought the sensitivity of modern instruments to about ten times that of early models.

Since this is a pressure-operated type of microphone, there are inherent irregularities in its characteristics from acoustic and mechanical phenomena. The microphone diaphragm is subject to certain resonance frequencies as well as the cavity. These tend to disturb the smoothness of the response characteristic. The sound waves striking and being reflected from the flat surface of the diaphragm cause pressure doubling, especially at high frequencies.

Below 500 cps this instrument is practically nondirective whereas at frequencies above 2,000 cps the directivity is noticeable. This directivity has a tendency to discriminate against h-f noise and reverberation, and, under certain conditions where

[1] Wente, E. C., *Phys. Rev.* 19, 498, 1922.

the studio does not accentuate the low frequencies, it has an advantage since the human ear responds more easily to background noise of higher frequencies than to lower frequencies.

The Western Electric 640A miniature condenser microphone unit[1] contains a diaphragm a fraction of an inch in diameter. The capacitance unit is mounted in one end of a tapered shell housing, of dimensions approximately 2½ in. in diameter and 7 in. long, which also contains the preamplifier. The weight of this microphone and preamplifier unit is 1¼ lb.

Published field-response curves indicate a rather uniform frequency-response characteristic from 40 to 10,000 cps with some dropping off of the higher frequencies as the angle is increased from an axis line normal to the diaphragm.

12. Parabolic Reflector Microphone. The use of a large concave reflecting surface mounted behind a microphone has been found to give the instrument pronounced
FIG. 14. Comparative axial response at 1,000 cps in millivolts per dyne per square centimeter. (*A*) Parabolic reflector; (*B*) dynamic-pressure-type microphone.

directional characteristics in the reception of sound waves. The system gets its name from the shape of the reflecting surface, a cross section of which contains a section of a parabola. By virtue of the microphone placement at the focus of the parabola of revolution or hollow paraboloid section, the sound waves striking the reflecting surface are concentrated upon the microphone diaphragm facing the inside of the paraboloid, resulting in increased sensitivity of the instrument in line with the axis inside of the paraboloid.

The use of the reflector, therefore, makes possible the placement of the instrument sufficiently far from the sound source so that it is practically equidistant from all the instruments or voices, with a result that the problem of securing proper balance and volume control is simplified. The directional characteristic makes it possible to swing the microphone and its reflector as one would a searchlight and in this manner follow the action on the stage of an auditorium or on the field of a sporting event. There is an increase in sensitivity along the line of axis of about 4:1, owing to the use of the parabolic reflector.

Since the reflector increases the sensitivity and makes it possible to locate the microphone at a greater distance from the source of sound, it is desirable that the output of the microphone should fall off rapidly if the sound originates at a point displaced more than 30 deg from the axis of the instrument; if this characteristic is obtained, reverberation and reflections in the studio or auditorium will have very little effect.

[1] Harrison, H. C., and P. B. Flanders, An Efficient Miniature Condenser Microphone System, *Bell System Tech. J.*, July, 1932, p. 451. Hopper, F. L., *J. Soc. Motion Picture Engrs.*, September, 1939, p. 278.

The h-f response may be increased as much as 15 db over the response at low frequencies by varying the position of the microphone in the reflector. However, in focusing the microphone, care must be taken to select the most useful frequency range, because at certain points of focus there is a tendency for sharp irregularities in the l-f response owing to cancellation between the directly received and reflected sound from the paraboloid reflector. In certain instances where the h-f absorption is considerable, the ability to accentuate the highs by refocusing proves very helpful.

Another distinct advantage of this directional microphone is its ability to disregard to quite an extent the acoustics of the room as it responds almost entirely to the sounds
FIG. 15. Axial frequency response of parabolic microphone with a focal length of 8 in.

upon which it is directly focused. In some cases another microphone without a reflector has been used with the parabolic microphone so that it may be faded in at certain times to make the reproduction sound more realistic. The parabolic microphone has been used to pick up sound from a certain section of a large crowd or audience at a sports event or to pick up the voice of a single individual at a time in an audience.

13. Effective Output Level. When a microphone is connected to an unloaded input transformer its power output cannot be expressed in dbm because no appreciable power is delivered by the microphone. Therefore one must arrive at a figure which, when combined with the conventionally measured amplifier gain, will give the correct level for the combination, called the effective output level. It differs from the EIA standard rating G_M in the value of sound pressure and source impedance. The EIA rating computation is based on a source impedance of 150 ohms for all microphones having impedances between 75 and 300 ohms, and on a sound pressure of 0.0002 dyne per sq cm.

FIG. 16. Frequency response on axis of parabolic microphones having various focal lengths.

The effective-output-level calculation is based on the nominal microphone impedance and on a sound pressure of 10 dynes per sq cm.

The EIA standard defines the system rating G_M of a microphone as the ratio in decibels relative to 0.001 watt per 0.0002 dyne per sq cm of the maximum electric power available from the microphone to the square of the undisturbed sound field pressure in a plane progressive wave at the microphone position. Expressed

mathematically,

$$G_M = \left(20 \log_{10} \frac{E}{P} - 10 \log_{10} R_{MR}\right) - 50 \text{ db}$$

where E = open-circuit voltage of microphone
P = undisturbed sound field pressure
R_{MR} = microphone rating impedance (150-ohm)

Electrical reference level = 0.001 watt
Sound pressure = 0.0002 dyne per sq cm

For all practical purposes the output level of the microphone is obtained by adding to G_M the sound pressure level relative to 0.0002 dyne per sq cm. The sound pressure level of the program material can be measured with any of the several available sound-level meters. The exact relationship between G_M and the effective output level is illustrated below for the case of the type 44-BX velocity microphone connected for 250-ohm output impedance.

G_M = −146 db
+ 94 db sound pressure level for sound pressure of 10 dynes per sq cm
− 2 db correction for difference in source impedance 250/150 ohms

Effective output level −54 dbm

14. Hum Pickup Level. An arbitrary standard 60-cycle a-c field of 10^{-3} gauss has been established as a reference. It is fairly representative of fields measured at typical microphone locations in broadcast studios. The hum level is referred to 0.001 watt and is calculated in the same fashion as the effective output level, using as the output voltage the voltage produced by the standard field. A high-quality microphone has a hum pickup level in the order of −120 dbm or less.

15. Microphone Calibration and Testing. The sensitivity of a particular microphone is generally expressed as the open-circuit output voltage generated at the microphone terminals for a unit sound pressure against its active element. The intensity of the sound waves impinging upon the active element may be evaluated as a pressure or force. This is usually expressed in dynes per square centimeter.

The actual voltage generated by the microphone being very minute (a very small fraction of 1 volt for a sound pressure of 10 dynes per sq cm against its element), the sensitivity may be expressed in minus decibels below a standard reference level. When it is desired to correlate this value with the amplifier gain, one would have to assume the microphone to be loaded with a matching impedance. This would result in dropping the output voltage to one-half the open-circuit value or a corresponding 6 db decrease in output.

The sound pressure at a particular point where a standard microphone is set up is sometimes measured by the Rayleigh disk method. This instrument consists of a light circular mirror suspended by a fine quartz fiber at an angle of 45 deg to the axis of the tube through which the sound waves pass. The torque produced on the disk mirror by the sound field is measured by the deflected beam of light focused upon it. For small angles of deflection, the rotation of the disk is proportional to the sound intensity in the tube and consequently to the intensity in the undisturbed field. The actual value of torque may be determined by a torsion head which has a tendency to return the mirror back to its original position.

Where a sound chamber having suitable acoustic properties to prevent reverberation, at the lower frequencies especially, is not available, wave response calibrations are made in open air in a quiet atmosphere. From a standard microphone calibrated in this manner, other instruments may be compared to it for characteristics.

In determining the response characteristic of a diaphragm-type instrument such as a condenser microphone, use has sometimes been made of the thermophone method, the thermophone consisting of two strips of gold foil mounted on a plate and fitted into the recess in the front of the microphone, the recess being entirely enclosed and filled with hydrogen. A d.c. upon which is superimposed an a.c. is passed through the foil and causes fluctuations in the temperature of the foil and the gas immediately surrounding it. These

fluctuations in temperature cause changes in the pressure on the microphone diaphragm, and the magnitude of the pressure developed on the diaphragm can be computed from the constants of the system. Thermophone calibration is often referred to as a pressure calibration, since it depends entirely upon the actual pressure developed on the diaphragm and hence does not take into account any effects which may occur when the microphone is used for actual pickup purposes. The response obtained by placing the instrument in a sound field of constant pressure is termed a *field calibration.*

The effect of the diffusion of the sound field and the tendency for most acoustic materials to be more absorbent at high frequencies appear to cause the microphone actually to respond more closely to the field calibration than to the pressure calibration.

Previous to the use of any microphone in an actual broadcast or rehearsal, it is carefully tested by speaking into it and having another trained individual listen to the quality of the sound reproduced through a high-fidelity amplifying and loud-speaker system. As compared to the results secured from a standard microphone of known high quality, the condition of the microphone under test can be determined.

The outputs of two or more microphones when connected to a mixing circuit should have the same phase relation so that the output of one will add to that of another. Therefore, all microphones used for broadcasting are tested for phasing, and each one is connected to its connector plug so that proper polarity exists with respect to other microphones when it is plugged into a socket or jack.

Correct phasing of two or more microphones may be checked by first connecting one microphone to an associated amplifier input and setting the volume control knob to secure a given output reading on the volume indicator while talking into the microphone. The second microphone is then connected in parallel with the first and with the same volume control setting; both microphones are held close together and the same procedure of talking into them is repeated. A decrease in volume and impairment in quality from the previous signal would indicate that the polarity of one microphone was incorrect, and a reversal of connections on its plug to provide correct phasing with respect to the other microphone is required as indicated by an increase in volume with two microphones properly phased. Phasing of all microphones used should be checked in this manner so that the phasing of each agrees with all others.

STUDIO TECHNIQUE AND MICROPHONE PLACEMENT

16. Studio Problems. A problem of vital concern to a broadcasting system is that of providing favorable acoustic conditions within its studio or auditorium facilities so that the effects of reverberant sound from the walls of the enclosures may be kept within desirable proportions in comparison to the sound reaching the microphones directly from the source. Of even greater concern are the problems involving correct placement of microphones with respect to the sound sources within the enclosures, to assure faithful reproduction of each voice or musical instrument, their significant overtones, and a pleasant blending of the groups of voices or instruments.

It is, therefore, by virtue of the selection of a microphone which will faithfully transmit all the actual sounds that occur within its range as well as the correct placement of it within a studio or auditorium having suitable acoustic characteristics that high-quality programs can be produced. Under optimum conditions of reproduction a broadcast listener would hear the same acoustic naturalness of the program from his loud-speaker as he would if he were to be transported to a favorable spot in the studio.

The major considerations involved in proper studio design such as soundproofing, ventilation, optimum dimensions, and suitable acoustical treatment of the walls have been given.[1] At present we shall be concerned only with the problems of microphone placement, assuming that favorable studio and auditorium conditions exist. Normally, these considerations would be as follows: adequate soundproofing that would

[1] Hanson and Morris, *loc. cit.* Sivian, L. J., *Bell System Tech. J.*, **10**, 108, 1931. Morris, R. M., and G. M. Nixon, Broadcast Studio Design, *RCA Rev.*, October, 1936. Nixon, G. M., *RCA Rev.*, January, 1942, p. 259. Content, E. J., and L. Green, Acoustic Design and Treatment for Speech Broadcast Studios, *Proc. IRE*, February, 1944, p. 72.

prevent undesired extraneous noises from entering a given enclosure, and suitable acoustical treatment of the walls and floor to provide equal absorption over a wide frequency range and give the enclosure in itself a uniform frequency characteristic. It is of considerable importance that the frequency characteristic of the studio or enclosure be considered for high-quality transmission because this characteristic is actually superimposed upon that of the microphone under conditions where the reverberant sound received by the microphone is appreciable as compared with that received directly from the source.

17. Single vs. Multiple Microphone Usage. During the first years of broadcasting, it was a usual procedure to use more than one microphone to pick up a program, especially under conditions where the broadcasting group was rather large. This was necessary on account of rather low microphone sensitivity and the inherently high noise level of the microphones used during that period requiring a placement of those instruments sufficiently close to the sound sources to overcome the inherent background noise. The combination of more than one microphone for making a pickup has a disadvantage in that the outputs from the several microphones used were not in proper phase relation with respect to the sound sources. This resulted in considerable distortion when the microphone outputs were combined and fed into a common amplifier.

Improvement in microphones to secure higher sensitivity as compared to inherent instrument noise level has resulted in the possibility of using one microphone at a time. Each microphone is located at a sufficient distance from the sound sources so that more than one microphone is not necessary to obtain a good acoustic balance from a particular group. The practice of using more than one microphone at a time has therefore been discouraged whenever possible because of the phase distortion in the sound field resulting therefrom. Under conditions where more than one microphone is used at a time, each should be properly phased or polarized with respect to others as mentioned above.

18. Microphone Placement. For diaphragm types of microphones, the directional characteristics at the higher audio frequencies may require the placement of the broadcasting group located in front of the diaphragm to be contained in an area formed by an angle of 30 deg on either side of the microphone axis.

The frequency characteristics of any diaphragm type of microphone are dependent upon the relative positions of the microphone and the sources of sound in front of the diaphragm. When the sounds approach at right angles to the plane of the microphone diaphragm, a uniform response over the desired range might be obtained. But, if the sounds approach from any other point, it will be found in general that the response will fall off with frequency. This characteristic indicates that response varies with the angular displacement of the sound source from the microphone axis. There is a high loss at the higher frequencies for high angular displacements from a point in front of the microphone. Since most musical instruments depend for their quality or timbre upon the presence of overtones, it is obvious that, if these overtones are discriminated against, the quality will be changed materially. Considering this loss in the higher frequencies with angular displacement and using a single microphone of the diaphragm type, all the musical instruments of a group should usually be kept within an angle of 30 deg either side of the microphone axis. Present-day microphones of the diaphragm type have uniform frequency response over much wider angles and permit arrangements of the broadcasting groups as shown in Fig. 17 within an angle of 45 deg on either side of the microphone axis.

Fig. 17. Microphone setup for large orchestra.

An individual source of sound such as a speaker, announcer, or musical instrument
should not be placed closer to the microphone than 1 ft. Greater distances are determined by the volume range of the voice or instrument and the relative volume desired with respect to the accompanying instruments.

One must consider that in different selections and different arrangements of the same selection the relative importance of the particular instruments may be changed considerably. Where desired prominence cannot be given to a particular group at a certain time using a single microphone, it may be necessary to fade-in another located near the group to be emphasized. A number of microphones can in this way be used, in the particular interval desired, to emphasize the particular musical instrument or
FIG. 18. Orchestra arrangements for use with a single diaphragm-type microphone.

instrumental group, the soloist, or the announcer. The control of individual microphone circuits for this arrangement is performed in the control booth by suitable mixing and switching devices. Extensive rehearsing accompanied by listening tests at a remote point are generally required to secure the desired balance for a particular setup.

In general, the volume range of certain instruments adjacent to one another permits their alliance into natural groups, each instrument of a group being placed approximately equidistant from the microphone. One group may contain violins, violas, and cellos; a second group, the piano, harp, flutes, and clarinets; a third group, the oboes, bassoons, and French horns; a fourth group, the string bass, tuba, timpani, and traps; a fifth group, the trombones and trumpets. In dance orchestras the guitar is usually placed in the first group, the saxophone in the third group, and the banjo with the fourth group.

There are many factors involved in securing the proper placement of vocal sound

sources or musical instruments before a microphone, particularly before a pressure or diaphragm type. While certain rules have been set up, they may serve only as a guide. Most satisfactory results are obtained by a combined study of the instruments as well as an actual setup of them before a microphone in a given enclosure. The result of actual listening tests by means of a high-fidelity speaker and monitoring system performed by one who has a trained ear for music or sound naturalness is a final check upon the proper placement.

19. Typical Studio Arrangement. A typical setup of a large orchestra before a directional microphone is shown in Fig. 17. The instruments are placed to obtain the desired balance for theater or auditorium work and to obtain the proper harmonic balance allowing for the microphone directional characteristics. The microphone is usually placed high above the floor, sometimes near the ceiling of the auditorium.

Present-day microphones, such as the unidirectional and cardioid types, are used to advantage since their response in the rear is very small. The string instruments in this setup, being the least powerful ones, are concentrated in the foreground of the group. The wood winds are next in line, followed in the background by the powerful brass and percussion instruments. In the arrangement the string tone of the orchestra is given a favorable position to produce a softness to the music which will not be overpowered acoustically by the heavy brasses and percussion instruments.

FIG. 19. Microphone arrangement for dance orchestra.

Figure 18*a*, *b*, *c*, and *d* shows various arrangements of instruments and voices before the pressure or diaphragm type of microphone. The directivity vs. frequency-response characteristic of this particular type permits the placement of the musical instruments within an area contained by an angle of 45 deg on either side of the microphone axis. In using this type of instrument the source of sound, speaker, announcer, or musical instrument should not be placed closer than 1 ft from the face of the microphone.

The bidirectional characteristics of the velocity microphone are advantageous in that the performers can be distributed on both sides of the instrument in a manner shown in Fig. 19. The uniform frequency-response characteristic of the instrument with directivity is an advantage in that the intensity of some instruments may be decreased without discriminating against their higher frequencies, simply by moving them at a larger angle with respect to the microphone axis.

An orchestral arrangement involving the use of a velocity microphone[1] is shown in Fig. 20.

The orchestral group in this arrangement was conveniently located on one face of the instrument. To prevent reflection from a wall directly in back of the microphone, the instrument is tilted at an angle of approximately 30 deg toward the orchestra. An exceedingly well-balanced pickup has been accomplished by this method.

20. Volume Controls or Faders. Volume controls or faders used in high-quality broadcasting circuits should have frequency characteristics which are uniform between 30 and 15,000 cps to prevent them from causing frequency distortion. Also essential is a very low noise level. This is normally -150 db or better. Proper shielding for protection against dust and dirt is necessary to maintain a low noise level, as well as to act as a shield against any stray r-f electromagnetic fields.

In Figs. 21 to 27 are shown various types of attenuating structures used in broad-

casting technique. The type shown in Fig. 21 is frequently used as a microphone fader and is commonly known as the LT structure. When used in multiple such as for mixing several microphone outputs, as in Fig. 22, sufficient resistance is inserted
FIG. 20. Velocity-microphone setup for large orchestra group.

in one output lead from each attenuator to maintain correct circuit matching. The bridged-T structure shown in Fig. 23 is used extensively for the same purposes.

The ladder attenuators maintain an impedance that remains practically constant in both directions through the middle of the attenuation range. Important features of this type of attenuator are its simplicity of design requiring fewer contacts and switches. The minimum attenuation setting of a ladder pad normally corresponds to its insertion loss, which amounts to approximately 2.5 db. Where an attenuation range is required extending from zero upward, the H or T structures are used. They are usually constructed with a minimum attenuation setting of zero.

FIG. 21. LT attenuator.

The T and balanced-H structures maintain a constant impedance in both directions when properly terminated. The balanced-H and ladder structures are used where
FIG. 22. Multiple-type LT attenuator.

the transmission circuits must be balanced to ground for the purpose of avoiding cross talk and noise that are present in unbalanced circuits. They are frequently used in broadcasting circuits as master gain controls. Figure 28 shows a high-imped-

ance voltage divider usually in the form of a gain control in the input circuit of a vacuum tube. This is a common type of gain control used on speech amplifier units.

Microphone fading is usually accomplished at high level or at the outputs of the preamplifiers and in a control booth beyond where programs originate in studios. For field pickups fading is sometimes accomplished directly at the outputs of the microphones. This, of course, requires attenuators of very low noise level. Microphones of the moving-coil dynamic and the velocity-ribbon types have constant low-impedance output over a wide frequency range and for this reason can be faded directly at their outputs.

Fig. 23. Attenuator of the bridged-T type.

The curves in Fig. 29 give resistance values of the branches of a T or H pad suitable for a channel having an impedance of 200, 500, or 600 ohms, the range of attenuation being between 2 and

Fig. 27. Balanced-H attenuator.

30 db. Similar curves for other impedances may be determined from the formulas published previously.[1]

Fig. 28. High-impedance voltage divider.

21. Volume Indicators. The volume level of an audio signal at any particular point in a broadcasting system is normally measured by means of a standardized instrument called the *volume indicator*. The components of the complete instrument consist essentially of a sensitive high-resistance voltmeter of the copper-oxide type, an associated T attenuator for extending the range of the meter to higher readings, and a variable resistor accessory to the attenuator provided for calibrating the instrument. The instrument scale is marked

[1] Johnson, K. S., "Transmission Circuits for Telephone Communication," Van Nostrand; and Lanterman, W. F., The Design of Attenuating Networks, *Electronics*, February, 1931.

in a logarithmic fashion, and superimposed upon this is an associated percentage scale. Two scales are provided, the A type tending to emphasize the vu readings and the B type in which the percentage readings are more prominent.
FIG. 29. Chart for H and T attenuator design.

While an oscillograph placed across the circuits at a particular point in the system would give a true picture of the rather complex wave shapes present from program signals, it would be a rather cumbersome and expensive method of indicating the characteristics of the signal, although it could be used if properly calibrated against a standard. However, through coordination between the broadcasting systems and the telephone company whose facilities were also involved, there was developed[1] a standard instrument of the indicating-needle type having characteristics most suitable for the purpose of indicating signal volume.

The standard volume indicator (Fig. 30*a* and *b*) utilizes a d-c instrument with a noncorrosive full-wave copper-oxide rectifier mounted in its case. Arranged for bridging, as in Fig. 30*a*, across a line, it has an impedance of about 7,500 ohms measured with sinusoidal voltage. Of this impedance 3,900 ohms is in the meter and about 3,600 ohms is external for the purpose of securing required dynamic characteristics.

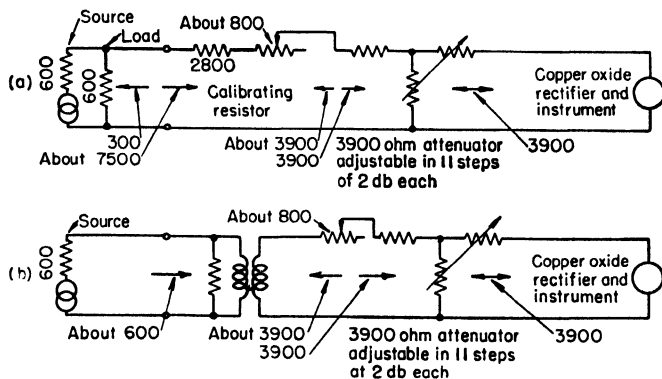
The dynamic characteristics are such that if a 1,000-cps sine-wave voltage of an amplitude to give a steady reading of 100 on the voltage scale is suddenly applied, the


FIG. 30. Standard volume-indicator circuit. (*a*) For bridging across a line; (*b*) low-impedance arrangement as for line termination.

pointer will reach 99 in 0.3 sec and then overswing the 100 point by at least 1.0 and not more than 1.5 per cent. The frequency response of the instrument is very good,

[1] Chinn, Gannett, and Morris, *loc. cit.* See also Chap. 13.

as is indicated by the fact that it does not depart from its 1,000-cps reading by more than 0.5 db between 25 and 16,000 cps.

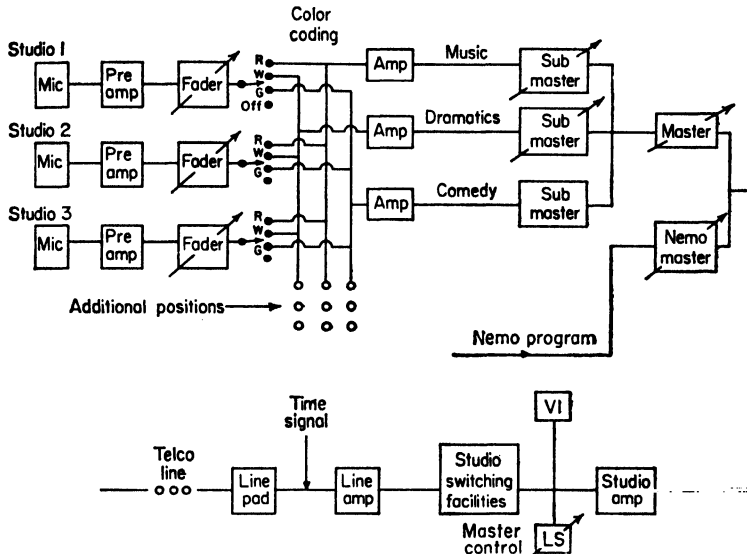
The standard volume indicator is calibrated to read 0 vu when it is connected to a 600-ohm resistance in which is flowing 1 mw of sine-wave power at 1,000 cps or *n* vu when the calibrating power is *n* db above 1 mw. However, owing to limitations in the present art, it has not been found practical to make an instrument of sufficient sensitivity to be calibrated to read 0 vu across 600 ohms with 1 mw, and therefore the instrument is normally calibrated by the application of 1.228 volts rms (4 db above 1 mw in 600 ohms) to the instrument in series with the proper external resistance to cause a deflection to the 0-vu or 100-scale point. The instrument therefore has sufficient sensitivity to be read at its normal 0-vu point on a volume level of +4 vu, which


FIG. 31. Equipment and facilities required for a single program channel.

is the minimum setting of the attenuator and volume indicator; for this reason the 1-mw calibration is correct.

For routine checking of the calibration of volume indicators, a "reference" instrument properly calibrated may be used in a simple comparison method.

To the terminals of a source of a-c voltage of adjustable output, the reference volume indicator and volume indicator to be calibrated are connected in parallel. The attenuators of both indicators should be set at +4 vu. The applied voltage is then adjusted until the reference-volume-indicator pointer is at the 0 vu or 100 mark. If the pointer of the volume indicator being checked is not then on the 100 mark, its calibration resistor should be adjusted until it reads the same as the reference volume indicator.

Since the standard volume indicator has been developed and standardized as a method of checking the volume of signals of complex wave shapes, it has associated with it the term vu. This term has been restricted to its intended use; hence, whenever a volume level reading is encountered expressed in so many plus or minus vu, it will be understood that the reading was made with an instrument having the characteristics of this standard instrument and expressed with respect to the reference level. Certain types of volume indicators, even when recalibrated to a 1-mw basis, will not give indications corresponding to those of the vu instrument on all types of program

waves owing to the particular characteristics of the instrument. The zero reference level for communication purposes is usually expressed as zero dbm. This level is based on a 1-mw signal of single-sine-wave frequency as measured in a circuit having a standard 600-ohm resistance termination. See also Chap. 13, Sec. 35.

22. Speech-input Amplifiers. These amplifiers are also termed *preamplifiers* or *microphone, line,* and *program amplifiers.* They comprise the apparatus necessary to increase the electrical energy output of the microphone or transcription reproduction to a sufficient level to permit its transfer by means of wire lines to the broadcast transmitter. The normal energy level of programs entering the wire lines or program loops is approximately +8 vu (+14 vu delivered from the line amplifier with a 6-db isolating pad). A schematic of the equipment shown in Fig. 31 shows positions of the microphone controls, volume indicators, monitoring amplifiers, and relay-switching systems.

Speech-input equipment is designed to have a substantially uniform response from about 30 to 15,000 cps and above. The maximum gain of such a three-stage amplifier from input to output is approximately 75 db. Input impedances are 62.5, 250, and 600 ohms, and the output impedances are 250, 500, and 600 ohms.

PROGRAM RECORDING FACILITIES

The essential parts of a large broadcasting system usually include the facilities for recording programs for the following reasons:

1. To have an accurate record or log of the program material actually broadcast from a station. This is known as *reference recording.*
2. To secure a record of a studio or special-events program at some distance over wire lines and thus be able to reproduce the program at a time most convenient for an audience which may be in a time zone a number of hours different from that in which the event takes place.
3. For production of recordings to use at small stations where wire-line facilities are not available.
4. The recording of an audition of a person or group of persons qualifying for a program part.
5. Production of sound effects such as crowd noise, for convenient use and introduction into a particular program.

23. Recording Equipment. The essential equipment required for producing high-fidelity recordings on magnetic tape or disk records consists of the following: For bridging a program bus by means of a multiple point switch there is a limiting amplifier of the type similar to that described in Sec. 48. It is the function of this limiting device to prevent overcutting of the record on high peaks. Following this are duplicate recording channels, each a program amplifier having linear amplitude characteristics and a uniform frequency response over a wide range. This amplifier normally has audio power-handling capabilities up to +46 vu so that high audio peaks are not distorted before reaching the cutter head. There is a standard volume indicator across the line following this equalizer since the cutting head is placed after the equalizer, the output of which drives the cutter head.

24. Sound on Disk Recording.[1] The direct method of disk recording utilizes aluminum disks usually 16 in. in diameter and 0.050 to 0.060 in. thick, coated with a cellulose nitrate compound (usually miscalled "acetate"). The cellulose nitrate coating is used as the medium for recording sound modulations. These disks are suitable for immediate playback.

For indirect recording it is the usual procedure to use soft wax records approximately 17 in. in diameter and from 1 to 2 in. thick. These records are later processed to produce a hard record approximately 16 in. in diameter and ¼ in. thick.

The sound record is cut in the highly polished surface of the wax disk by means of an electromechanical recorder. The technique of cutting wax records is similar to making standard electric phonograph records. The standard speed for common phono-

[1] See Chap. 19, Secs. 111 *et seq.*

graph records is 78, 45, and 33⅓ rpm while for broadcasting records it is usually 33⅓ rpm. This speed with a 16-in. disk gives a playing time from 10 to 15 min.

Both types of records are usually cut with the spiral proceeding from the outside edge of the record toward the center, similar to making standard electric phonograph records.

25. Variation of Frequency Response on Disks. In recording on a disk revolving at a constant angular velocity, the cutter stylus is placed near the outside edge of the record, and, as the engraved spiral of the sound track progresses toward the center of the disk, the velocity with which the stylus travels on the disk is decreased. This velocity is directly proportional to the radius between the center of the disk and the position of the stylus. Now, for most satisfactory reproduction of the higher frequencies, the stylus must travel with sufficient velocity over the disk to provide sufficient space in the groove to permit satisfactory engraving of the h-f pulsations of very short duration. Therefore there is a tendency for more satisfactory engraving of the higher frequencies near the outer edge of the disk than toward the center. In other words, for a given cutter engraving on a disk of constant rotational speed, the frequency response one may reproduce from a disk is more satisfactory near the outer edge of the disk and is less satisfactory, especially at high frequencies, as the stylus moves toward the center. For this reason, if high-fidelity results are to be obtained, the groove containing sound modulation should not be closer to the center of the disk record than 5 in. for 78-rpm recording and 8 in. for 33⅓-rpm recording. Medium to good results are obtained with the groove containing the sound modulation at a radius on the disk of not less than 2½ in. for 78-rpm and 4 in. for 33⅓-rpm recording. For a given playing time it is sometimes possible to keep this minimum radius, cutting more grooves per inch, sometimes as many as 160 in lateral and vertical disk engraving.

26. Lateral and Vertical Disk Engraving. In the lateral system the groove depth is kept constant, and the engraving stylus moves in a horizontal fashion to produce undulations in the sides of the groove. The groove spacing therefore must be sufficient to prevent the stylus from cutting into adjacent grooves at the low frequencies.

The vertical system utilizes an engraving stylus moving in a vertical direction. The groove depth varies with the mechanical modulation, whereas the groove width is kept more or less constant, with the result that the groove spacing can be kept closer with a correspondingly greater duration of playing time.

In Fig. 32 are illustrated waves produced in disk-record grooves under conditions of "constant-amplitude" and "constant-velocity" recording. The wave marked 1 illustrates constant-amplitude engraving produced by a constant sound level regardless of frequency at the cutter. In this case the recorded amplitude is the same for all frequencies.

The constant-velocity system utilizes constant vibrational velocity of the stylus in the record groove under influence of the cutter head. In this case the amplitude of the wave is inversely proportional to the frequency. The wave marked 2 illustrates undulations in the record groove produced by constant-velocity recording, producing an increase in amplitude with a decrease in frequency for a constant sound-level input (assuming that the entire system from the microphone to the cutter head has a uniform frequency characteristic). In this instance, where amplitude $= v/kf$, the amplitude of a wave frequency f of 100 cps would be one-half that of 50 cps for a constant velocity v. At the lowest frequencies, therefore, the amplitudes would be excessive if sufficient amplitudes of the higher frequencies are to be produced in the record groove. Since the groove spacing would have to be made considerable to avoid "groove crossover" or "echo" effects in adjacent grooves, due to excessive amplitudes at the lower frequencies, it is customary to cut records at constant amplitude for frequencies below some point between 350 and 800 cps and at constant velocity for frequencies above this point. This is illustrated as wave 3, a solid line. The transition frequency between constant-amplitude and constant-velocity recording, normally some point selected between 350 and 1,000 cps, is called the *turnover point*.

To produce a constant-amplitude cutting characteristic up to the turnover point

and a constant-velocity cutting beyond, it is necessary to utilize corrective equalizers depending upon the particular type of cutter head used. In some cases the response characteristic of the electrodynamic cutter head itself is a contributing factor in the production of the constant-amplitude and constant-velocity range as well as the turnover point. This is illustrated in Fig. 33.

Commercially, direct recording has become of great importance because of its advantages of immediate playback and cheapness when producing disks in small quantities. While the nitrocellulose coating is essentially softer than the pressed
FIG. 32. Characteristic of waves produced with the constant-amplitude and the constant-velocity systems of recording.
FIG. 33. Frequency response of cutter head based on optical measurements of the stylus-tip motion for constant input.

records manufactured by the electroplated soft wax process, as many playbacks as 100 may be secured from a nitrocellulose disk with a well-designed lightweight reproducer. A substantially flat frequency response may be recorded on, and reproduced from, these disks over a range of between 50 and 10,000 cps and higher near the outside portion of the disks. It is good practice where very high-fidelity reproduction is required on 33⅓-rpm disks to use the outside portion of the disk to compensate for the loss of the higher frequencies in reproducing as the pickup moves toward the center of the disk or to divide time into two or more disks, thus permitting reasonably high linear recording velocity of the cutter stylus. A volume range of approximately 55 db has been obtained from nitrocellulose disks using the lateral system of recording and reproducing. With satisfactory operating conditions over-all distortion of the combined recording and playback operations is less than 5 per cent. This over-all distortion is also a function of engraving velocity, decreasing as the velocity is increased, also decreasing with a decrease in engraved depth.

Flutter is a term used to describe vertical modulation produced in the recording groove due to the bounding of the cutter head at a frequency of approximately 30 cps. It is normally caused by mechanical response of the recording head and its associated supporting-arm mechanism under excitation from building noise and other l-f rumble. In observing reflections from record grooves created by a single source of light, the effects of flutter can be noticed in the form of spokes or long spiral patterns extending from the inside over the recorded surface to the outside. Under a microscope this vertical modulation may be seen as a varying width of the cut groove. Manufacturers supply stabilizers which assist in the elimination of flutter.

When recording on nitrocellulose disks, an air-suction nozzle is provided near the cutter to remove shavings or shreds so that they will not interfere with the engraving process and also to provide for safe disposal of this highly inflammable material. Care must be taken to avoid dust, fingerprints, or grit from entering the engraved surfaces of the disk. Otherwise there is a tendency for increased noise. It is customary to engrave 120 grooves per inch on these disks, although 96 and 112 and as high as 160 grooves per inch have been used. This number is fixed by the lead screw of the recording machine. The groove depth engraved on this type of disk is normally about 0.0015 to 0.002 in. Commercially, it has been possible to secure recordings of this type having a noise level 50 to 60 db below the maximum modulated signal, although the average record has only a 35- to 40-db spread between noise and modulated signal. By the method explained below for processing soft wax from which pressings are made of a hard material, nitrocellulose disks may be similarly processed for the purpose of making a large number of pressings.

The indirect recording method requires considerably more equipment and time to manufacture the pressed disks than the direct method described above. However, for mass production, pressings can be made considerably more cheaply than single records by the direct process.

27. Necessary Equipment. Equipment necessary for wax disk recording consists essentially of a machine lathe especially designed to turn the wax record clockwise at a uniform speed, which is 33⅓ rpm for broadcasting work. The carriage of the lathe is driven with a lead screw carefully machined to move the recorder holder at a predetermined rate while cutting the wax record. The lead screw is driven through a gear train which regulates the number of grooves cut per inch, usually 86, 92, 98, 112, or 120. A recorder holder provides the necessary support for the electrical recorder.

A horizontal turntable, driven through a vertical shaft, is provided for supporting the wax record. The vibration of the driving motor is eliminated on different lathes by various methods.

28. Disk Records. The grooves of a disk record are ordinarily spaced 92 to 160 per inch. For 92 grooves per inch this allows about 0.011 in. from center to center of the groove, of which 0.006 in. is the width of the groove itself. The maximum lateral motion of the stylus is thus limited to about 0.0025 in. on either side. Generally, 0.002 in. should not be exceeded. Cutters usually used are designed as constant-velocity devices. In practice such cutters have this characteristic only above 300 cycles or higher. Below this point the amplitude is independent of frequency. If the maximum amplitude for a 300-cps wave is equal to 0.002 in. on either side of the center, then a 1,500-cps amplitude for the same electrical input level would be 0.0004 in.

The shape of the groove varies somewhat in commercial practice, but it is approximately 0.006 in. wide and 0.0025 in. deep. The pitch of the groove is generally 0.010 to 0.011 in., leaving a space between grooves of about 0.004 in. With only this space available, the maximum safe amplitude is something less than 0.0025 in., if the walls of the groove are not to be cut too thin.

Cutting stylus consists of a sapphire, synthetic ruby, or other hard point fastened to the lower end of the stylus arm. One end of the sapphire has a rounded point about 0.002 in. radius and standard cutting angles of approximately 70 or 90 deg for the sides.

The advance ball is a small cylindrical sapphire, ground spherically at one end and

held in an adjustable mounting attachment to the recorder. This ball supports the weight of the recorder, and the arm, being adjustable, permits regulation of the depth of the groove on the wax.

Playback reproducer is provided to permit playing back the wax record immediately after it is cut for rehearsal work and test. This usually renders the wax unsuitable for processing, and for this reason two wax records are usually provided for each recording channel, one of which can thus be used for playback and the other for processing. The pressure of the needle on the wax is generally adjusted to between 15 and 20 g.

A needle provided for playback from the soft wax is designed differently from the ordinary needle used for the finished hard record. The Western Electric type has a point of 0.003 in. radius. The needle is constructed on a mandrel, ground to a smooth finish, and the point given a chromium plate to improve wearing quality.

Checking Speed. The periphery of the turntable is usually divided with vertical lines, so that a neon lamp, operating from a 60-cps source, may be used as a stroboscope to observe the turntable motion. The lines on a standard turntable are usually arranged so that with 60 cps on the lamp, as the turntable rotates at exactly 33⅓ rpm, the lines will appear to be stationary. If faster than 33⅓ rpm, the lines will advance slowly, and, if slower than 33⅓ rpm, the reverse will be the case. This check of the speed is usually made with the wax record on the turntable.

Checking the Damping Action. A method of checking the instantaneous constant speed may also be used to check correct damping of the turntable. With the turntable rotating at normal speed, the oscillator for supplying 60-cps source to the neon lamp may be adjusted until the vertical lines appear stationary. If the disk is now touched lightly by hand, the line or spot observed will appear to shift its position owing to momentary load. As soon as the hand is removed, the line or spot observed should come back to its original position. Observing the movement will determine whether the turntable has insufficient damping or too much damping.

Determining the Starting Point. Disk records for radio broadcasting use are usually cut in clockwise rotation from the outside in, similar to ordinary phonograph disk records. To obtain a definite starting point for the records when in use, the first groove is spaced an appreciable distance from the rest of the cut. This is obtained by a coarse speed cam actuating the lead screw at the start of recording. As the lead screw makes its first complete revolution, it moves the recorder under the influence of the cam until the recorder is in its normal cutting position.

29. Wax-suction Equipment. This equipment is provided to furnish a means of removing the shavings from the wax record during recording. The suction tube is so placed that the shavings thrown off by the stylus are carried away from the face of the wax. A central suction system is usually provided in studios having several recording channels. This usually consists of a turbine suction pump with pipe lines leading from a central suction point to a separator tank placed in each recording room. In some smaller installations, an individual bell jar, with a small suction motor, is used for each recording machine.

30. Wax Preparation. Two types of waxes are generally used in sound recording, those having a working temperature of 75°F and those with a working temperature about 90°F. Matthews type M, 75°F working temperature, is perhaps most commonly used. It is considered good practice to maintain the room temperature for the type M wax around 75°F when recording.

The procedure for preparing the wax consists briefly of the following steps:

1. At the center of the wax, which is usually indicated by a cross mark, a 9⁄32-in. hole is drilled to a depth of ½ in.
2. A coarse cut is made for a depth of about ⅛ in. on one face of the wax and repeated as necessary to obtain a perfectly flat surface. The wax is later reversed, the first cut surface becoming the base for the finished wax.
3. On reversing the wax, a hole is cut from the other side to meet the hole drilled on the bottom.

4. A coarse cut is now made on the top surface and repeated where necessary to produce a smooth and flat surface. The wax is now ready for the final shaving or polishing cut, which is done with a sapphire or ruby cutting tool.

5. The face of the shaving knife is usually set at an angle of between 40 and 50 deg to its line of travel, depending upon the particular design of the knife. Its rounded end is toward the center of the wax. The cutting face of the knife is set at an angle of 90 deg to the surface of the wax. The turntable revolves in a counterclockwise direction.

6. The suction nozzle is placed close to the cutting knife, about ⅛ in. from the front face and $\frac{1}{32}$ in. above the cutting edge.

7. The best finishing speed is usually determined by experience, but generally ranges from 150 to 160 rpm. The finished cut on the wax should give a perfectly polished surface free from ripples or blemishes of any kind.
FIG. 34. Recording equipment layout for two type 73-B recorders.

31. Record Processing. Briefly, this consists of various steps, after obtaining the soft wax record, to produce the final hard record for commercial use. A complete description of each step would go beyond the limits of this section. The following are the essential steps in this process:

1. The surface of the engraved soft wax disk is rendered conductive by spreading a very thin, extremely fine conducting powder, such as metallic powder, over its surface; by the finer processes of depositing silver from a solution of silver nitrate; or by sputtering pure gold of very minute thickness on the surface. This coating is for the purpose of forming one electrode in the electroplating process.
2. Electroplating of this record with a sheet of copper $\frac{1}{32}$ to $\frac{1}{16}$ in. in thickness deposited on the wax. The negative electroplate obtained is separated from the wax and used to hot-press a molding compound, such as shellac, mixed with a finely ground filler. The first electroplate obtained is called a *master*.
3. Two test pressings are made from the first master, after which it is electroplated with a positive.
4. From this positive, sometimes referred to as an *original*, a metal mold or *stamper* record is made.
5. From the record, duplicate originals may be made and, from them, duplicate molds or stampers. By thus making a number of duplicates, it is possible to protect the original master from injury.
6. From each stamper it is possible to obtain as many as 1,000 finished pressings.

Generally, it may be said that the duplicating process reproduces everything on the original wax engraving to such a fine degree that the only difference one may observe is in the materials, one soft wax, and the other a harder, more durable plastic, composed of shellac, vinyl, or acetate compounds mixed into a filler having very little

abrasive property. The surface of these manufactured records is considerably harder than the nitrocellulose coating on metal-covered disks used for direct playback and, with a sufficiently light reproducer, will reproduce with good quality up to 1,000 playings.

32. Re-recording. It is common practice to select desired portions of a sound record by a process of re-recording. This is done with both disk and film records. Either can be played on standard reproducing equipment, which then serves as the input to the recording system, in place of the microphones. Special re-recording equipment is also used, one type consisting of a film reproducer and a film recorder combined in a single instrument and actuated by a single motor. The output of the reproducer photocell is, of course, returned to the recorder light valve in the same casing only after it has passed through an external amplifier. This instrument is used to copy on 16-mm film a sound track that was originally recorded on 35-mm stock; optical reduction, however, is also used for that purpose. Duplication of records and films is often called "dubbing."

Re-recording is used to superimpose special sound "effects" upon a record. For this purpose two or more reproducing systems are connected as a parallel input to the recorder amplifier. The method offers superior control over the relative volume of such sounds as gunshots, background music, or storms and, moreover, tends to reduce the cost of production. A library of "effect" records is maintained at many studios.

Originals intended for re-recording are sometimes made abroad by cutting a lateral track in discarded film, which is reported to be entirely serviceable for this purpose and to withstand many playbacks without damage.

33. Electrical Recording Machines. It is essential that a recording machine of a precision type should have a constant speed. For this reason it is usually driven by a synchronous motor. The mechanical inertia of the revolving table assists in keeping the rotational speed constant, the speed regulation of the disk being usually better than 0.3 per cent. It is customary to mount the driving motor on vibration dampers in such a manner as to prevent the motor vibration from reaching the revolving table. Vibration from the motor shaft is kept from reaching the shaft of the revolving table by using either belt drive, rubber differential speed rollers, or both. The spacing of the grooves cut on the disk is controlled by gear trains and the lead screw which moves the cutter head toward the center of the disk. The number of grooves engraved per inch can be set by means of the gears. A suction tube is provided for removing the shaving or thread produced while engraving. A microscope and groove illumination lamp facilitate examination of the engraved grooves. A playback pickup arm is generally provided in addition to the engraving cutter mechanism to permit playback of the record for quality checking.

34. Recording Heads or Cutters. The essential requirements of a recording head suitable for producing high-quality recordings are as follows: (1) freedom from amplitude distortion in producing undulations on the disk record, (2) suitable frequency-response characteristic over a range of 40 to 10,000 cps to produce constant-amplitude and constant-velocity recording over the frequency ranges required, (3) freedom from mechanical resonance which would tend to cause overcutting, and (4) reasonably good efficiency in transformation of complex electric wave energy into mechanical vibration of the cutting stylus.

There are numerous types and designs of cutting heads manufactured for recording sound on disk. The most common in present-day usage are the electrodynamic and the piezoelectric crystal types.

Electrical recorder heads provided for disk recording are generally designed so that the average linear velocity of the stylus (which may be expressed as a constant $\times$ the frequency $\times$ amplitude) is proportional, over a wide range of frequencies, to the impressed voltage, or $v = kfe$. The method of damping the moving system varies with different recorders.

A drawing of an electrodynamic type of recording cutter is shown in Fig. 35*a*. With a modulated current passing through the winding of this instrument, the arma-

ture produces and transfers to the cutting stylus mechanical undulations conforming with those in the electric wave, except that the amplitude is altered somewhat by mechanical and electric means. In Fig. 35*b* is illustrated a high-fidelity recording head. This cutter head utilizes a band-pass mechanical network terminated in a dry mechanical resistance material. The balanced armature is centered by means of a tempered steel spring. It is supported on knife-edge bearings upon which the lateral stylus motion is centered. Nicaloi is used for the pole pieces of the permanent magnet.
FIG. 35. (*a*) Electrodynamic type of recording reproducer; (*b*) high-fidelity recording head.

The frequency-response characteristic of this cutter head is shown in Fig. 33. Below 800 cps, frequencies are controlled to hold amplitude constant, the stylus velocity decreasing as the frequency is reduced. Above the 800-cps point the response curve shows constant-velocity motion well over a frequency of 10,000 cps. It is possible by electrical means to move the turnover point in this curve from 800 cps to a lower frequency of, say, 500 cps if desired.

While the electrical input impedance of the cutter head itself is approximately 5 ohms, an electrical-impedance compensating network can be secured to retain the total input impedance of 15 ohms throughout a wide frequency range. A high-quality amplifier having a power output of 10 watts or more is recommended for driving this cutter head.

FIG. 36. Circuit for correcting characteristic of recording head.

35. Crystal Cutting Head. This type of recording head utilizes a 5-ply Bimorph Rochelle-salt crystal to drive the sapphire stylus to engrave sound waves on disk records. For the constant-amplitude recording range the voltage applied to the crystal of the cutter head is normally 75 volts rms, while for the constant-velocity range of recording it is about 150 volts rms. Since the internal impedance of the head is rather high normally, 159,000 ohms at 100 cps, the actual power consumed by the crystal is rather small, being less than 1 watt, although the power output recommended from the driving amplifier is considerably more.

A corrective equalizer is required with the cutter for constant-velocity recording above 350 cps. Under correct operating conditions the manufacturer shows that this cutter has a frequency characteristic substantially flat within ±3 db between 30 and 10,000 cps.

A sapphire cutting stylus is recommended for use with the cutter head. For most conditions of recording the groove depth is 0.0025 in. for cutting soft wax and 0.0015 to 0.002 in. for nitrocellulose records.

36. Measurement of Frequency Response. By examination of the frequency-response curves of the various component parts of a recording system the over-all performance of the system can be checked. The program microphones and amplifiers which feed the recording head are measured in a conventional manner with a standard sound source, beat-frequency oscillator, output meter, or cathode-ray oscillograph. Under these conditions the output of the amplifier at the terminals of the cutting head is usually flat within ± 1 db between frequencies of 40 and 10,000 cps.

The recorder cutting head, however, usually has a sloping frequency characteristic (Fig. 33). The response of the cutting head alone has been measured by supplying constant level tone at various frequencies to the head and, by means of a tiny mirror attached to the stylus, reflecting a beam of light into a phototube. It is usual practice to measure the response of the cutter and disk material together.

This consists in making a recording of the output of a beat-frequency oscillator held at constant voltage at the cutter terminals. Frequencies usually recorded in order from outside to inside are as follows: 10,000, 9,000, 8,000, 7,000, 6,000, 5,000, 4,000, 3,000, 2,000, 1,500, 1,000, 800, 500, 300, 200, 150, 100, 80, and 50 cps. The completed record is then removed from the turntable; and under a concentrated single source of light, the reflection of light source as seen in the grooves shows peculiarly patterned shapes similar to their descriptive name "Christmas tree."[1] The pattern is symmetrical about the radius of the disk. It is actually a graphic representation of the frequency responses of the cutter and disk material together. The radius of the disk is the axis of frequency, the end of the pattern nearest the center being the lowest frequencies. The width of the pattern measured perpendicular to the disk radius is proportional to the undulations of the groove. This in lateral recording corresponds exactly to modulation depth. This phenomenon is due to the reflection of light over a wider band, the greater the ratio of modulated groove width to depth.

Inasmuch as good reproducing equipment usually has flat characteristics, the Christmas-tree pattern may be produced with straight sides from the turnover frequency of, say, 500 to 7,000 cps. Below this, it is customary to compensate the loss of low frequencies by boosting them with electrical filters in the reproducer. If it is noticed that pronounced peaks are in the pattern, the cutter head may be adjusted or filters inserted to produce the response characteristics required.

37. Record Reproducing Facilities. Transcribed programs generally originate in studios located separately from those in which recording is done. It is quite evident that, if full advantage is to be taken of the high-quality program material recorded on disk records, the transcription or producing equipment must also be of the precision type.

The transcription turntable is generally driven by a high-torque synchronous motor cushion-mounted within the console or cabinet. The motor shaft is flexibly coupled to the main turntable spindle. Speed regulation is reduced to a very small value for both rotational speeds of 33⅓ and 78 rpm by means of flywheel inertia and a mechanical filter on the drive shaft.

Speed reduction of the RCA type BQ2A turntable is accomplished by means of a heavy-duty ball-bearing speed-reduction mechanism operated by a button located at the rim of the turntable disk. Noise and vibration pickup is kept at a minimum by cushion-mounting the motor and spindle-housing and cushioning the suspension arms.

Special consideration is generally given to the design of a satisfactory tone arm and reproducer head for high-fidelity reproduction. The reproducer head must be light in weight and in pressure on the groove of the disk. Normally the pressure exerted by the diamond point stylus as measured by means of a spring balance or postal scale should not exceed 2 oz. A more desirable weight is less than 1½ oz. A lightweight tone arm and reproducer head assists in the reduction of record hiss or scratch noise and also the reduction of high frequencies especially near the center of the disk. Lightness also assists in securing more playbacks from a recording, since a lateral reproducer having a stylus which operates too stiffly or having too great a pressure on the disk tends to erase the higher frequencies from the record groove.

[1] See Chap. 19, Sec. 111.

Commercial reproducer heads generally utilize electrodynamic or piezoelectric principles as electric generators to convert mechanical force supplied by the groove modulation through the stylus assembly to the electrical generator element.

The reproducer of Fig. 35a is equipped with a permanent diamond point, the radius of which corresponds to the 0.0023-in. standard for lateral cut nonabrasive high-fidelity records. The armature is of the clamped-reed type. The two upper air gaps are filled with nonmagnetic material and are inactive. A linkage having a 6:1 leverage ratio is provided since the armature impedance is too high to be directly coupled to the record groove through the stylus. A diamond point is secured in the lower end of an extremely light pivot-arm spring supported vertically but rigid laterally. The pivot arm is thus permitted to rise without lifting the entire head. In the direction of useful motion transmitted to the armature the linkage has a minimum of compliance with a resultant cutoff of about 9,000 cps. This peak is reduced by means of a block of loaded rubber arranged as a selective damper approximately adjusted for the resonant frequency.

A shunt capacitance located within the tone arm is generally connected across the pickup coil to react broadly with the inductance, increasing the response through the upper frequency range. An equalizer may be placed directly at the output of the pickup head to compensate for losses in the record modulations.

The piezoelectric type of lateral disk-record pickup head utilizes a Bimorph crystal under torsional strain to convert mechanical modulations of the record groove into electrical waves. The sapphire stylus used with this reproducer is set in a small screw which fits the thread of a hollow magnesium block. The motion of the chuck is converted into a torsional strain in a bronze wire. This in turn conveys a twisting force to the Bimorph crystal sealed hermetically within a compartment. The emf produced at the electrodes of the crystal is developed from the twisting force produced by the stylus and attachment mechanism.

This type of reproducer head is normally rather light in weight, resulting in a stylus pressure of approximately 1 oz on the disk. It may be used for reproducing either constant-amplitude or constant-velocity recordings, the type of electrical compensating network required being dependent upon the particular characteristics of the recordings.

38. Orthacoustic System. There is a limitation on the amplitude of the lower frequencies recorded upon a disk. This is corrected by a sloping characteristic in the response curve below the turnover point, brought about either mechanically in the recording head or electrically with a suitable network. The undesirable needle h-f hiss is another limitation to be overcome for a satisfactory recording and reproducing system, as well as the l-f rumble caused by the turntable and building vibration, etc.

FIG. 37. Orthacoustic-recording-characteristic curve which gives preemphasis to high frequencies.

In the NBC Orthacoustic system, recording and reproducing units are individually compensated to offset characteristics of each other and thus create a reproduction which is very nearly the equivalent of the original sound. Below 100 cycles the characteristic of the recorder system is made constant-velocity by electric means. This tends to give preemphasis to the low frequencies. Then it rises from 100 to 500 cycles on a constant-amplitude basis in accordance with the mechanical and electrical characteristics of the cutter.

Above 500 cps a preemphasis above a constant velocity is given to the high frequencies, especially over the noise frequency range.

The necessary characteristic for reproduction is the inverse of this curve, or Fig. 37,

secured by electrical and mechanical means, especially those of the transcription head itself. An over-all response curve is produced which is flat over the desired range.[1]

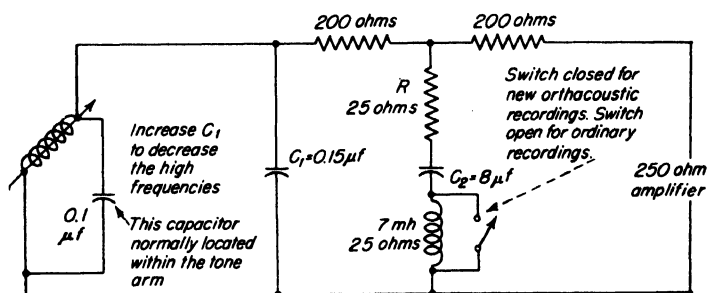
39. Magnetic Tape Recorders.[2] The magnetic system of recording sound patterns upon a record of tape by magnetization is illustrated in a simple manner in Fig. 39.


FIG. 38. Compensation filter for orthacoustic reproducer.
FIG. 39. Essential parts of magnetic tape recorder.

The magnetic tape moves rapidly past the pole pieces of an electromagnetic recording head while the windings are energized by the a-f signal source.[3] In traversing the windings of the recording head magnet, the audio signal currents of complex wave shape cause a fluctuating field to exist in the pole pieces. Corresponding longitudinal magnetic patterns are impressed in the moving tape.

[1] EDITOR'S NOTE: Production of the "microgroove" 33⅓-rpm records by Columbia Broadcasting System utilizing new record material virtually eliminated the noise common to the old 78-rpm disk records and, at the same time, made it possible to record upward of 20 to 30 min on a single side of a standard 12-in. disk. Extraordinary expansion of the record market for home-entertainment purposes resulted.

[2] See Chap. 19, Secs. 121 *et seq.*, of this handbook.

[3] Ranger, R. H., Magnetic Tape Recorder for Movies and Radio, *Electronics*, October, 1947.

Reproduction of the audio signal impressed by magnetism on the tape is accomplished by connecting the output of a reproducing head electromagnet through an amplifier to a loud-speaker or other electroacoustic translating device and running the magnetized tape past the pole pieces of the reproducing head in the same direction and at the same rate of speed. Under these conditions, the magnetic patterns in the passing tape create fluctuations in the magnetic field of the pole pieces and generate voltages in the windings which correspond to the wave form of the original audio signal.

Recording sound on a magnetic tape offers certain advantages over other methods especially in applications where records of a temporary nature are desired. In this case, the same medium may be used over and over again to make new recordings when old ones are no longer required. The sound record on magnetic tape may be erased and it may again be made ready for reuse by simply causing it to pass through a steady high-frequency magnetic field which causes the old signal to be erased an instant before the new signal is impressed.

FIG. 40. Tape-magnetization process.

Another advantage is in making continuous long-duration recordings upon a single magnetic tape medium, thus avoiding the procedure of having to change recording disks at intervals when using the sound-on-disk system. A sound record on magnetic tape may be stored away for an indefinite time without fear of deterioration. The tape record may be played back hundreds of times without appreciable loss of quality, which is an advantage over disk recordings which depreciate rapidly when used continuously.

40. Magnetic-recording Medium. The recording tape used for magnetic recording consists of finely divided iron oxide particles deposited on a plastic strip having dimensions usually about $\frac{1}{4}$ in. wide and 0.002 in. thick. The strip is manufactured of a plastic compound which has excellent properties of strength and durability to withstand the mechanical stresses produced during the recording and reproducing processes. For the purpose of illustration, assume that the tape is moved through a field in which a magnetic force alternates in accordance with a sine wave as illustrated in Fig. 40. The molecules of the iron oxide particles are oriented according to the direction and magnitude of the magnetic fields. The pattern of the audio signal stored in magnetic form on the tape is shown.

FIG. 41. Magnetization characteristics of magnetic tape.

The magnetization curve of the iron oxide particles of the tape is similar to that in Fig. 41. It should be noted that near the origin of the curves a very nonlinear condition exists. The signal recorded upon the tape under these conditions would not be directly proportional to the signal voltage applied to the windings of the recording head and a high amount of distortion would result when the signal was reproduced.

By superimposing a high-frequency constant-amplitude bias signal upon the audio signal to be recorded, this distortion can be reduced considerably. Usually the frequency of this bias voltage is selected to be about five to seven times the highest

a-f limit of the recorder. This is necessary to prevent beating between the bias and the harmonics of the recorded signal. For example, a magnetic recorder capable of reproducing up to 15 kc would require a bias voltage having a frequency of about 100 kc. During the instant of time that the tape is in the gap of the recording head, the bias voltage causes the magnetizing characteristics of the iron oxide to follow the dashed-line loops, as illustrated in Fig. 41. These are sometimes referred to as *minor hysteresis loops*. Coinciding with the movement of the tape from the gap, the effect of the magnetic field caused by the h-f bias diminishes to zero. The iron oxide coating of the tape then assumes a permanent magnetization. This is known as *remanent induction*, which is determined by the gap flux at the instant this particular part of the tape leaves the gap. Following the recording process, the tape contains a pattern of magnetic flux proportional in magnitude and direction to the audio signal recorded.

41. Magnetic Recording Head. The magnetic field is produced in the gap of the recording head over which the tape passes. An incomplete ring-shaped electromagnet forms the recording head, which is usually of the appearance shown in Fig. 42. The gap is formed by the discontinuity of the ring, which is made of high-permeability material to form the core of the electromagnet. The gap is usually filled with a nonmagnetic substance to form a smooth surface over which the tape passes.

FIG. 42. Recording head.

42. Magnetic Reproducing Head. The electromagnetic head used for reproducing the audio signal is quite similar in construction to the recording head. When the tape is moved past the gap of the reproducing head, the magnetic flux on the moving tape induces a voltage into the winding of the reproducing head. This is proportional to the number of turns on the winding and the rate of change of flux as produced by the moving tape.

For most satisfactory results, the gap in the reproducing head should be as small as possible. A good rule is to make it of a physical length equivalent to less than a wavelength of the highest frequency to be reproduced, which would be less than 1 mil. As the gap is decreased in width, however, the induced voltage is decreased and for this reason there is a practical limit to the minimum width of gap to maintain a signal-to-noise ratio that is of adequate proportions.

The audio signal induced across the windings of the reproducing head may be calculated from the following:

$$E = B_m V \sin (\pi\omega/\lambda)$$

where E = voltage induced
B_m = maximum flux density of recording material
V = velocity at which tape moves across reproducing head
ω = width of head gap
λ = wavelength of the signal on the tape

This expression indicates that the voltage produced across the windings of the reproducing head will increase directly with an increase in velocity of the tape and with a decrease in the wavelength.

When the velocity of the tape and the gap width are constant, the voltage delivered from the windings of the reproducing head will be directly proportional to the frequency under conditions where the wavelength on the tape is large compared with the width of the gap, and as a result the curve of output voltage vs. frequency is shown by the solid line A in Fig. 43. Because of an increase in the electrical losses of the core material as the wavelength nears the dimensions of the reproducing head gap, the actual output voltage drops off at the higher frequencies and follows the curve shown by the dashed line.

The problem of providing an over-all flat frequency-response characteristic for the

recorder is solved by an equalization circuit.[1] Series R and C of proper values connected across the input of one of the earlier stages of the reproducing amplifier as a solution provide an h-f droop characteristic that is inverse to the characteristic of the reproducing head.

The h-f response characteristic of the recorder is extended further by providing additional equalization in the recording amplifier. This is in the form of a frequency-boost circuit designed to compensate the dropping off of the high-frequency end of the reproducing-head characteristic because of excessive core losses.
Fig. 43. Output characteristics of the reproducing head.
Fig. 44. Equalization and over-all response of reproducing system.

43. Magnetic-recorder Components. The parts that are essential to a tape-recording setup are: (1) the tape and its transport mechanism including the driving motor; (2) the erase, record, and reproduce heads; (3) the h-f bias oscillator; (4) the record amplifier; (5) an audio input source; (6) a loud-speaker or telephones for monitoring; (7) a cabinet; (8) a power supply; and (9) miscellaneous mechanical controls and electric switching systems.

Magnetic tape is available upon standard-size plastic reels having nominal diameters of 7 and 10½ in. which contain the tape in lengths of 1,200 and 2,400 ft, respectively. The standard tape speeds are 3¾, 7½, and 15 in. per sec. The speed of 3¾ in. per sec will provide in high-quality recorder units a satisfactory response up to 7,500 cps. This slower speed has the advantages of a longer "full-track" playing time of 2 hr and 8 min for a tape length of about 2,400 ft. It is available on a 10½-in.-diameter standard reel. At a tape speed of 7½ in. per sec it is possible to secure acceptable response up to 10,000 cps with a full-track playing time of 1 hr and 4 min per 2,400 ft of tape and for a speed of 15 ft per sec good response of 15,000 cps is obtainable with a full-track playing time of 32 min.

The tape is used full-track where one signal only is recorded on the full length of tape. The tape can also be used "half-track" by recording the signals on both sides simply by reversing the tape on the reels. If half-track operation is used, twice the playing time becomes available for a given length of tape but there is, of course, the disadvantage of having to reverse the tape on the reel to play the entire length of the recorded signal.

The tape is moved by a capstan driven by a mechanical speed reduction, usually with belts and pulleys, from the shaft of a synchronous motor. It is customary for the motor to be of multiple speeds such as 1,800 or 900 rpm, thus simplifying the problem of changing the tape speed. A braking system is required on the tape-transport system to maintain a constant tension in the moving tape. The over-all speed regulation of the transport system is required to be a small fraction of 1 per cent to provide satisfactory operation of the recorder unit with respect to "flutter" and

[1] Korner, Otto, Frequency Response of Magnetic Recording, *Electronics*, August, 1947.

"wow" defects. These are usually in the order of 0.3 per cent rms or less. The flutter and wow measurements include all components between the frequency range of zero to 300 cps using an rms meter calibrated to read the peak value of a constant-amplitude sine-wave flutter. In the process of rewinding the tape on a reel, facilities are provided to increase the speed tremendously to effect a saving in time.

One of the keys to the design of a satisfactory tape-recorder unit lies in the recording and reproducing heads. They must be constructed in such a way as to record and reproduce the magnetic patterns on a tape with minimum distortion and maximum signal-to-noise ratio. For full-track operation, the peak record level is defined as that in which the over-all (input to output) rms harmonic distortion does not exceed 3 per cent when measured on a 400-cps tone assuming that noise is measured when erasing a signal of peak recording level in the absence of new signal. Thus, the bias and erase noise are included, as well as playback amplifier noise. Furthermore, it is assumed that all frequencies between 50 and 15,000 cps are measured.
FIG. 45. Relation between tape speed and frequency response.

For full-track operation, the peak record level as compared with unweighted noise should be at least 50 db for a tape speed of 3¾ in. per sec to 60 db for a tape speed of 15 in. per sec.

The reproducer head is a most critical part of the tape-recording unit because signals recorded on tape are of low intensity. It requires approximately 60 db of amplification to bring the peak recorded signals up to a level of zero dbm. Inasmuch as the dynamic range possible with tape recorders approaches 60 db, the weakest signals are nearly 130 db down or on levels that are slightly higher than the thermal noise in some vacuum tubes.

While the record head is generally constructed quite similarly to the reproducer head, a key to proper design lies primarily in the width of the gap in the high-permeability ring. This problem has been explained in Sec. 41.

The erase head contributes to satisfactory operation of a tape recorder by providing the removal, as nearly as possible, of the magnetic patterns previously recorded. The h-f field supplied by the bias oscillator provides sufficient energy to cause the erase head to remove by magnetic saturation the audio signals to be erased.

The record amplifier of a high-quality tape-recording unit must have high gain, a high amplified signal-to-noise ratio, and a low inherent amplitude distortion. Equalizers giving the required over-all frequency response with preemphasis on the higher frequencies are required to compensate h-f losses caused by magnetic saturation of the iron oxide particles as the tape passes through the recording-head gap.

A typical characteristic of a record amplifier is shown in Fig. 45. It should be understood that the separate equalizers are switched into the circuit to conform with the tape-speed requirements.

A bias signal of a frequency in the order of 70 to 100 kc is combined with the audio signal being recorded to improve the magnetic remanence of the magnetic coating on the tape. The ratio of the intensity of the bias signal to the audio signal is usually 1:2 or less.

Excellent characteristics of the reproducer amplifier are required to provide high gain, high signal-to-noise ratio, and low inherent amplitude distortion to the amplified audio signal that passes through it. The amplifier must have an equalizer in one of the earlier stages to give preemphasis to the lower frequencies to offset the natural characteristic of increasing voltage output with respect to frequency caused by the tape passing through the reproducer head. The over-all effect required to provide a flat over-all frequency-response characteristic for the recording unit has been explained previously and is illustrated by the curves shown in Fig. 44. The typical frequency-response characteristics of the reproducer amplifier of a high-quality tape recorder are shown in Fig. 46.
FIG. 46. Playback amplifier response magnetic tape recorder.

44. The Complete Magnetic Tape Recorder. In Fig. 47 is shown a schematic diagram of the electronic circuits which comprise the Ampex Model 350 magnetic tape recorder. This unit will accommodate tape speeds of 3¾, 7½, and 15 in. per sec. The over-all frequency-response characteristics are (1) ±2 db over the frequency range of 50 to 7,500 cps at tape speed of 3¾ in. per sec; (2) ±2 db from 40 to 10,000 cps for a tape speed of 7½ in. per sec; and (3) ±2 db from 30 to 15,000 cps. The peak record signal-to-noise ratio at full-track tape speeds of 7½ and 15 in. per sec is 60 db and for half-track it is 55 db. The other important operational characteristics are within the ranges previously explained.

45. Wire Lines. Wire telephone systems are employed almost exclusively for the national distribution[1] of programs to the various stations connected on a network.

The frequency band which is transmitted over long-distance program circuits extends from about 100 to about 5,000 cps; to transmit music with improved fidelity a wider band than the above is desirable. A few circuits are at present available which extend the band down to 30 or 50 cps and extend the higher range by 2,000 or 3,000 cps. Program transmission circuits must be designed to handle wide ranges of volume. At present the volume range is limited to some 25 or 30 db, from about +8 vu down to about −22 vu. Obviously, since the dynamic range of a symphony orchestra is about 60 db, the wire-line circuit necessitates some compression of the dynamic range, especially on long network circuits.

46. Standardization of Transmitting Levels. To obtain optimum conditions from the standpoint of noise and cross talk, it is desirable to transmit program material into

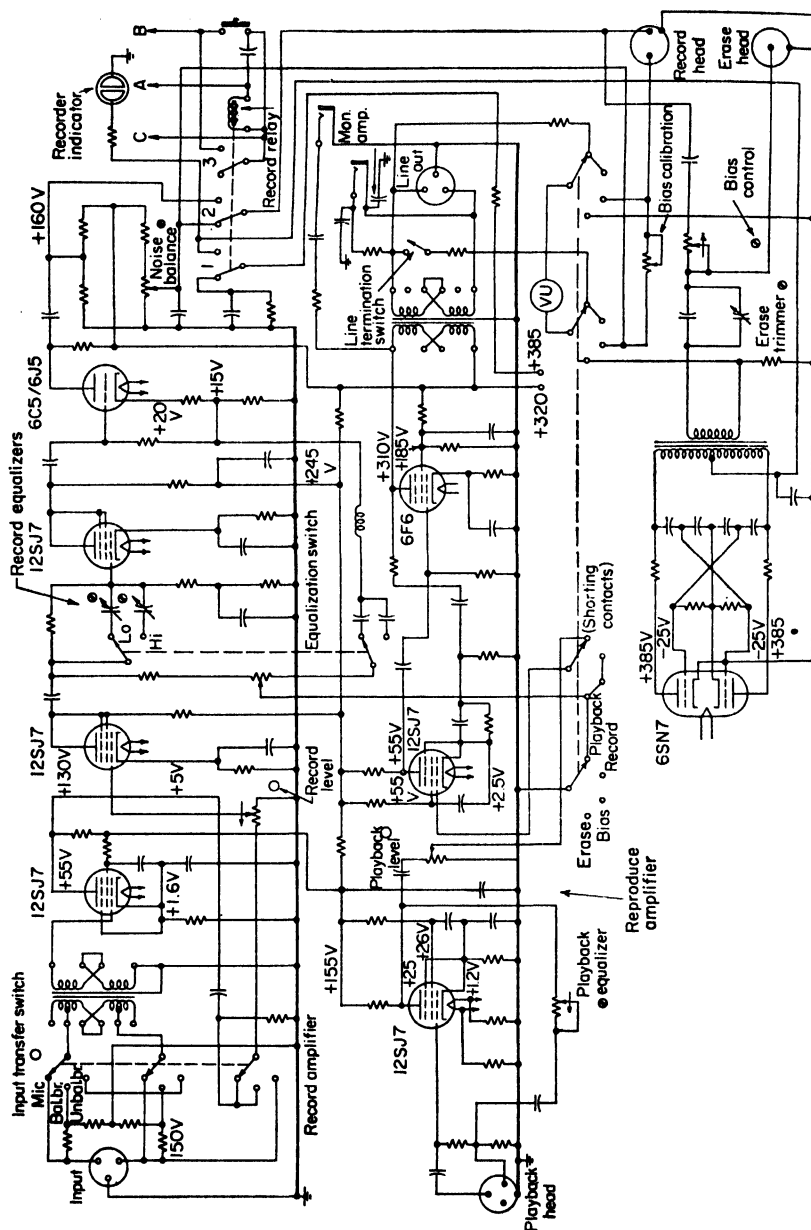
[1] Clark, A. B., Wire Line Systems for National Broadcasting, *Proc. IRE*, **17**, 1998, November, 1929.


FIG. 47. Simplified schematic diagram of Ampex Model 350 magnetic tape recorder.

loops at as high volumes as practicable. Telephone-company experience has demonstrated that in general +8 vu is about the highest volume of program material that can be tolerated in a local cable plant of the kind in which broadcasting loops are routed, from the standpoint of interference with other circuits. In view of these conditions, therefore, +8 vu (+14 vu output of amplifier followed by a 6-db pad) is

the standard volume level for transmitting to loops in local telephone cables. The isolating pad is for the purpose of isolating the amplifier from the telephone-company loops.

RADIO FACILITIES

47. A-f Equipment. The process of transferring programs from the main control room of the studios to the broadcast transmitting station is generally accompanied by a considerable reduction in the program signal level. Attenuation caused by the wire line upon which is added that caused by the line equalizer lowers the signal intensity as much as 25 db. A line equalizer consists of a specially designed network containing correctly proportioned values of L, R, and C. Irregularities in the wire-line frequency characteristics are smoothed out by the equalizer to produce a uniform frequency response of the wire line over as wide a range as practicable.

To increase the level of the incoming signals to a sufficient intensity to drive the first tube of the speech amplifier of a broadcasting transmitter, a line amplifier is required. This amplifier is usually of a high-quality limiting type having sufficient gain to raise the audio program signal to a level of approximately +15 vu. At this level it enters the first speech-amplifier stage. The line equalizers, line amplifiers, variable attenuators, volume indicators, monitoring amplifiers, microphone for making local announcements, together with their switching equipment and jack panels, are normally mounted on shielded racks in a room called the *control room*. The shielding of the room itself sometimes consists of an outside-grounded copper screen containing within it a floating copper screen.

48. Limiting Amplifier. A special type of amplifier normally used in the speech-input layout at the broadcasting transmitter is of the compressing or limiting type. This amplifier automatically reduces the channel gain whenever the program peaks become excessively high. Thus it tends to prevent overmodulation. As a result, distortion due to transmitter overmodulation can be avoided while at the same time the average modulation can be raised with a corresponding audio power gain at the receiver. This is noticeable especially at low passages of program material where background noise may become objectionable.

By rectifying a small portion of the program signal output, a bias voltage control is provided on a program signal amplifier. This action does not just cut off the program peaks, but it reduces the gain and then allows it to rise slowly to normal.

The signal voltage is amplified and then rectified in a diode with a result that a variable d-c bias voltage appears across a resistor in series with the bias voltage to the grids of the first stage of the amplifier. With an increasing signal, the bias becomes more negative and the output of the amplifier is reduced. This action does not occur, however, until the audio signal level applied to the control tube exceeds the fixed bias of this tube.

A potentiometer across the secondary of the input transformer is utilized as a variable-input control from which the corresponding input level at which the compression takes effect is varied. Owing to the high gain of the amplifier (54 db), the beginning of the compression may be as low as −40 vu. Provision is also supplied for adjustment of the output of the amplifier by means of a potentiometer in the input of the second amplifier stage. By means of this control the output level can be set anywhere within the range of −30 to +15 vu.

To compress sudden peaks of the program wave, the control circuit must function very quickly. The time constant of the circuits involved is such that the reduction in gain occurs in 0.001 sec. To prevent the gain from fluctuating at low audio or syllabic frequencies, a delay circuit is provided to allow the compression bias voltage applied to the grids of the tubes in the first stage to leak off slowly and return the amplifier gain to normal in about 7 sec. This delay has been set by listening tests to prevent introduction of distortion or to destroy speech inflections.

The amplifier has an output of +30 vu with 18 vu compression. The frequency response is flat within ±1 db from 30 to 10,000 cps.

49. Program monitoring facilities are a very essential part of broadcast station equipment. In broadcasting technique, *program monitor audio* refers to a monitoring

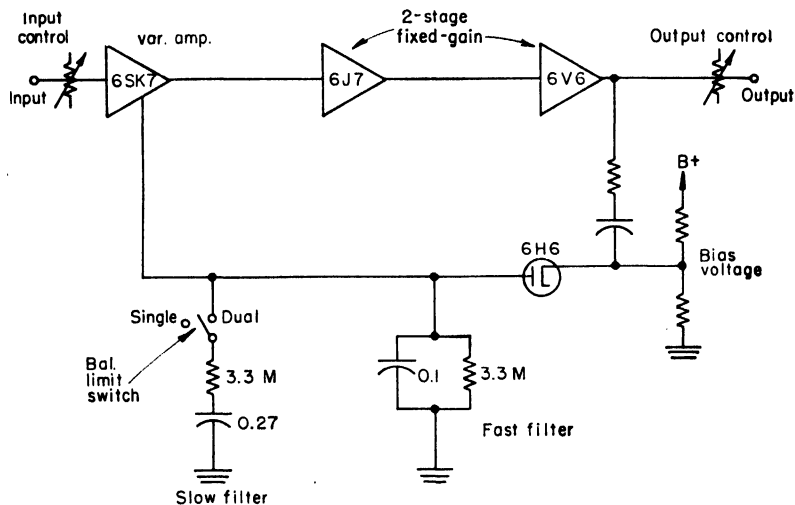
check on the audio signal input to the transmitter, whereas *program monitor radio* refers to a check on the demodulated signal secured by rectification of the carrier envelope as produced at the broadcast transmitter output. By switching from the *input signal* to that produced by rectification of the modulated transmitter carrier, the station personnel can determine by listening tests and measurements the relative


Fig. 48. Limiting amplifier, RCA BA-6A.

amount of distortion produced in the broadcasting station equipment. For monitoring the outgoing program the personnel normally listens to the program monitor radio as produced by demodulation of the signal at the antenna system. This ensures that all portions of the audio and radio transmitting equipment, as well as the antenna system, are functioning. This is indicated by monitoring loud-speakers or oscillographs.

Facilities for program monitoring are provided in a room suitably constructed and acoustically treated to provide a favorable place for listening tests in the judgment of quality. This may be either the transmitter room itself or an adjoining room called the control room where the speech input is normally located. The equipment for monitoring the audio signal consists of high-quality audio amplifiers, the gain of which can be regulated for proper signal volume; high-quality loud-speakers; and associated switching equipment. The frequency response of the entire system should be flat over a range of between 30 and 12,000 cps and higher. Additional to this equipment for program monitoring radio is a well-designed monitoring rectifier capable of demodulating the carrier signal as picked up at either the output tank circuit of the radio transmitter or at the antenna, preferably the latter.

Fig. 49. Antenna monitoring rectifier circuit.

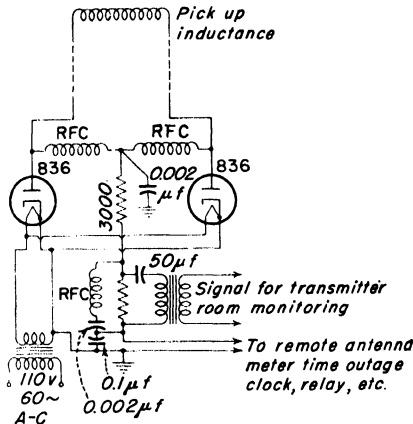
Schematic diagrams of two types of antenna monitoring rectifiers, shown in Figs. 49 and 50, illustrate single-ended and push-pull types, respectively. These rectifiers are equipped with circuits enabling them to be used as the remote antenna current-meter rectifier, to close a carrier-on relay or time-outage clock relay as well as the monitoring signal for oscillograph or loud-speaker. In coupling such rectifiers as shown to an antenna circuit, precautions are usually taken to prevent the generation of even and odd r-f harmonics into the antenna circuit as produced by rectification. Under certain conditions such harmonic generation and radiation from the antenna system may create interference on the harmonic frequencies. For this reason, the push-pull type when inductively coupled to a high current point of the antenna system


FIG. 50. Push-pull antenna monitoring rectifier.
FIG. 51. Characteristic of monitoring rectifier; i_p is total plate current.

has considerable advantage over single-ended types, in that even harmonics are not as pronounced.

For rectifying the envelope of a carrier wave to secure a signal for loud-speaker monitoring or for modulation measurements with an oscillograph, it is essential that the linearity characteristics of the monitoring rectifier between the impressed voltage and the plate current be substantially straight throughout the operating range. The unit must also have a uniform frequency-response characteristic to provide reproduction of the signal without frequency distortion.

Diode rectifier tubes are used extensively for monitoring radio telephone signals. As an individual element of the monitoring rectifier, the diode itself is not a linear device since the internal resistance of the diode decreases as the anode voltage is increased. The selection of diode tubes having low internal voltage drop and the introduction of sufficient resistance in the plate circuit are required in the design of a monitoring rectifier of satisfactory linear characteristics. Linearity may be further improved by application of a constant positive bias in the plate circuit so that the diode draws steady plate current over the most nonlinear lower portions of the curves. In Fig. 51 these design features are illustrated for a 5V4G diode, which is a particularly good type for monitoring rectifier use owing to its low internal voltage drop. Tubes of higher inverse peak voltage are often required for rectifiers of higher power-handling characteristics and to withstand voltage surges (such as those caused by lightning) from an antenna circuit.

The percentage distortion of a rectifier may be approximately calculated from the dynamic characteristic by using a formula similar to that used in calculating percentage distortion of triode amplifier tubes.

50. Frequency Monitor. This instrument is required to measure the amount of deviation of the carrier from the assigned frequency. The FCC rules under Sec. 3.59 state that the operating frequency of each a-m broadcast station shall be maintained within 20 cps of its assigned value. Under Sec. 3.60 of the FCC rules, the frequency monitor is subject to FCC approval with respect to stability and accuracy. The General Radio type 1181A frequency monitor illustrated in Fig. 52 is an approved type operating within the specified limits. It contains a frequency-standard oscillator utilizing a quartz crystal together with a tube (6SJ7) in a circuit having excellent frequency stability.

The oscillator drives a 6AC7 buffer amplifier with very light coupling between them. The output of the buffer is coupled to the grid of a 6SQ7 mixer, where it is mixed with voltage from the broadcast transmitter. This voltage is picked up at some stage of the transmitter below the one modulated, is amplified by a 6AC7, and coupled capacitively to the mixer. The oscillator is adjusted to a frequency of 1,000 cps off that of the transmitter carrier. Hence the output of the mixer is a difference frequency of 1,000 cps plus or minus the transmitter deviation frequency. The frequency thus produced is amplified and passed through a 6SQ7 clipper-limiter tube to produce a square wave of constant peak-to-peak amplitude.

The square-wave voltage is amplified by a 6V6 tube circuit and passed to a voltmeter. This latter instrument is a full-wave differential diode voltmeter which indicates the potential difference between the mid-points of two series resonance circuits. In this manner equal potentials are indicated at exactly 1,000 cps, and currents flow at other difference frequencies actuating the meter accordingly over the normal range of ± 30 cps deviation which is the direct scale reading of the meter.

51. Modulation Monitor. Section 3.56 of the FCC rules requires that each broadcasting station shall have an approved modulation monitor in operation at the transmitter to measure the degree of modulation of the transmitter and for furnishing instant warning when the degree of modulation exceeds a selected specified value.

In Fig. 53 illustrating circuits of a modulation monitor, the a-m r-f signal to be monitored impressed across diode 6AL5 is thus rectified. The average value of d.c. is indicated on the carrier meter. This is proportional to the average carrier voltage. The average component of voltage across a load resistor in the 6AL5 excites two indicating devices: (1) the meter M_2 calibrated to read modulation percentage and decibels directly and (2) a flasher and alarm circuit for providing a warning when the degree of modulation is exceeded.

The modulation-indicating meter is excited in the following manner: The audio component secured from the first diode is rectified by the second 6AL5 diode detector and charges C_2. The voltage across C_2 is impressed across the first grid circuit of the 12AU7 voltmeter stage which has the indicating meter M_2 in its plate circuit. Circuit constants are made such in this instrument that the a-f peaks on the r-f carrier are as indicated by meter M_2. The neon flasher is operated by the relay tube, an 884, which is in turn driven from the first tube under the same audio component from the tube that is used for operating the indicator meter system. If desired, the instrument may be used to operate an auxiliary alarm when the modulation peaks rise to an excessive value.

Modulation indicators are usually calibrated by means of a pure sine-wave modulating signal applied to an accurate cathode-ray oscillograph and checked against the indicator. The frequency response must necessarily be flat over the audio range used to ensure accuracy of measurement over the range.

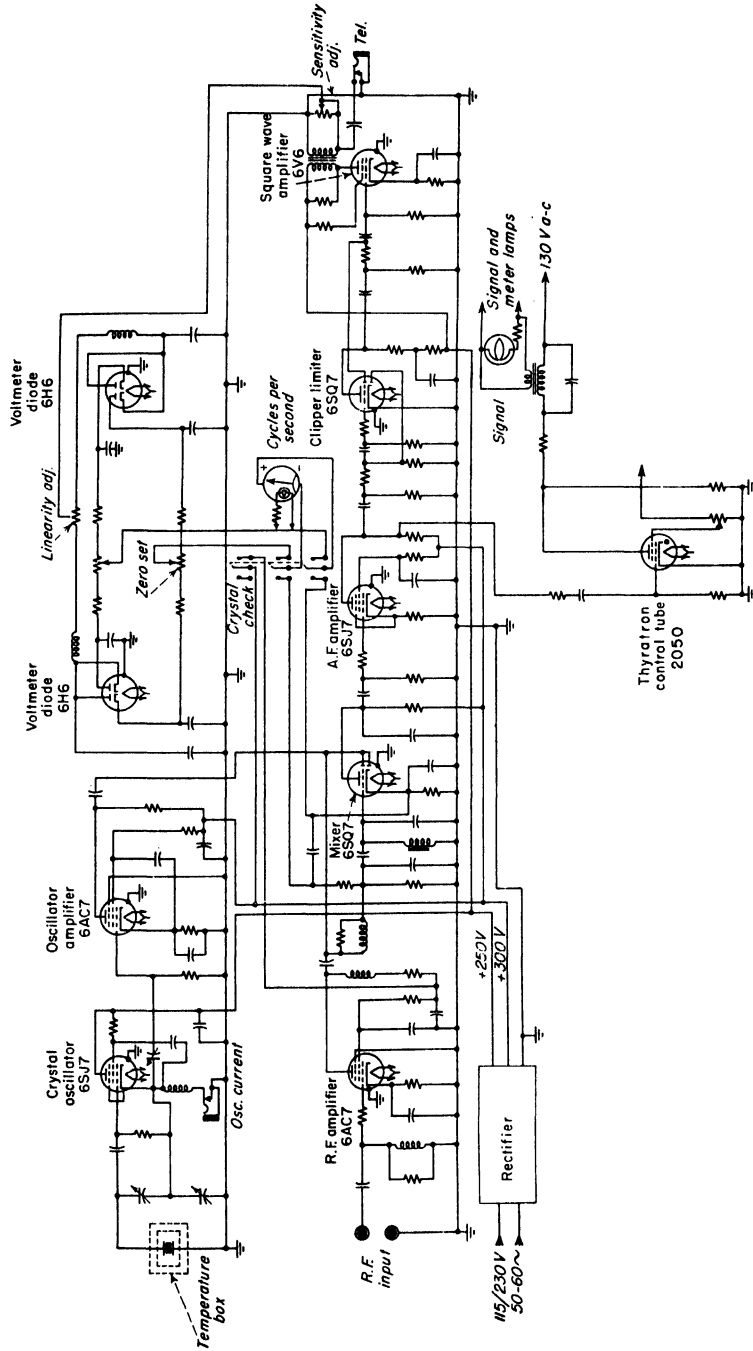
According to Sec. 3.55 of the FCC rules, a licensee of a broadcast station will not be authorized to operate a transmitter unless it is capable of delivering satisfactorily the authorized power with a modulation of at least 85 per cent. When the transmitter is operated with 85 per cent modulation, not over 10 per cent combined a-f harmonics shall be generated. Under Sec. 3.46 (FCC rules) design recommendations state that total a-f distortion from microphone terminals, including microphone amplifier, to antenna output should not exceed 5 per cent harmonics (voltage measurements) when modulating from 0 to 84 per cent and not over 7.5 per cent harmonics (voltage measurements of arithmetic sum) when modulating 85 to 95 per cent (distortion shall be


FIG. 52. Schematic General Radio type 1181A frequency-deviation monitor.

FIG. 53. Simplified schematic diagram of RCA BW66E a-m monitor.

measured with modulating frequencies of 50, 100, 400, 1,000, 5,000, and 7,500 cps up to the tenth harmonic or 16,000 cps or any intermediate frequency that readings on these frequencies indicate is desirable).

The operating percentage of modulation of all stations is normally maintained as high as is possibly consistent with good quality transmission and good broadcast practice.

RADIOBROADCASTING TRANSMITTERS

Production of a broadcasting signal that will afford a means for conveying speech and music to a broadcast listener involves the generation of a constant r-f carrier upon which there are superimposed audio frequencies in the form of side bands, the intensities of which conform as nearly as possible with those contained in the sound produced in the studio. The production of such a signal may be accomplished by several methods[1] of modulation.

In American broadcasting technique the amplitude system of modulation is used exclusively in the band 550 to 1,600 kc. The advantage of a.m. for transmission in this band lies in the production of a modulation envelope containing but a single pair of side bands, thus permitting station channel separation of 10 kc.

Compared with the a-m system, phase and frequency modulation produce an infinite number of side bands. It is evident that greater channel separation is needed and for this reason f-m stations have been assigned to the v-h-f part of the spectrum.

The primary requisites of a transmitter satisfactory for the band 550 to 1,600 kc under the present rules of the FCC are as follows:

1. Satisfactory carrier frequency stability well within the allowable FCC tolerance of ± 20 cps maximum deviation.
2. Amplitude and frequency response characteristics providing low over-all signal distortion.
3. Suitable safety devices to avoid hazards to operating personnel and electrical circuits and equipment complying with the National Electric Code.
4. Minimum carrier noise level, approved electrical metering facilities; minimum r-f harmonic frequency power output; and freedom from parasitic frequency emissions.
5. Low operating costs requiring an over-all high-operating efficiency with respect to power input, low approved power-tube operating expenses, and economical operating personnel requirements.
6. Durability, simplification of adjustment, and maintenance (requiring accessibility for repairs).
7. Reliability of service providing for continuous operation with a minimum of interruptions at rated carrier power output, modulated within legal limits.
8. Satisfactory dimensions for given power output providing for minimum installation and building costs.
9. Low initial transmitter and installation costs.
10. A pleasing appearance.

A trend is toward transmitters having high-level modulated and high-efficiency linear power amplifiers for producing the desired high-quality broadcasting signal with minimum operating expense.

52. International Broadcasting. Transmitters for this service are operated at high frequencies and for this reason are considerably different in design from transmitters operated in the 550- to 1,600-kc band. They are used with directive antennas having a power gain of 10 or more, and have carrier powers up to 200 kw 100 per cent modulated.

R-F CIRCUITS

53. R-f Amplifier Neutralization. One of the essential adjustments in an r-f amplifier circuit to obtain stability and prevent self-oscillation is accomplished through neutralizing the grid-to-plate capacitance of the triode power tubes.

For the purpose of neutralizing an amplifier stage such as the final r-f power amplifier first remove plate voltage from it and apply normal r-f excitation to the grid circuit. Tune

[1] Roder, Hans, Amplitude, Phase and Frequency Modulation, *Proc. IRE*, **19**, 2145, December, 1931.

the grid circuit to resonance in the usual manner. Next connect a low-power (5- to 10-watt) high-resistance lamp across one or two turns of the plate tank inductance. The leads to the lamp should be very short and provided with clips for convenience. Next tune the plate tank circuit to resonance with the grid exciting voltage frequency as indicated by maximum brilliance of the lamp. The circulating current in the plate tank circuit which lights this lamp includes the coupling effect of the grid-plate capacitance of the tube.

The neutralizing voltage of opposite polarity is obtained by connecting to the opposite end of the grid or plate tank circuits, as the case may be. The magnitude of the voltage used to neutralize the grid-plate capacitance current is regulated now by adjusting a neutralizing capacitor. As the neutralizing capacitor is varied, the lamp will change brilliancy, and, when correct balance is obtained, the lamp will be at practically zero brilliancy. As neutralizing capacitance is changed, some slight corrections in plate-tank tuning and in grid tuning may be necessary, owing to interactions of these two circuits. Always tune to resonance by maximum lamp brilliancy and neutralize for minimum brilliancy.

When best results are obtained by the lamp method, remove it from the plate coil, and, if more accurate adjustment is required, a low-range r-f ammeter should be inserted in series with the tank circuit. By using a meter, maximum accuracy is obtained by tuning the circuit to obtain absolute minimum current.

Since the effect of coupling between successive stages greatly affects the neutralizing, the adjustment should be made with all circuit conditions and couplings as nearly final as possible.

An entirely different neutralizing system consists of an effective inductance shunting the grid-to-plate capacitance of the amplifier tubes. Suitable d-c blocking capacitors are provided to prevent the plate voltage from reaching the grid through this neutralizing inductance.

Neutralizing adjustments with this shunt inductance may be accomplished with a high-resistance lamp or thermomilliammeter attached to the output tank circuit in much the same manner as was described for capacitor neutralization except that neutralization is accomplished by adjustment of the shunt inductance. This system has great advantages over the neutralizing capacitor method especially where it is desirable to keep circuit tank capacitance and the corresponding kva/kw ratio to a low value. This is the case where stabilized degenerative feedback is applied through an amplifier stage wherein a minimum phase rotation with frequency is required.

FIG. 54. Theoretical curves showing push-pull class B amplifier operation.

54. Class B Linear R-f Amplifiers. The operation of a push-pull class B r-f amplifier may be understood by a study of Fig. 54. Here it is shown that plate current drawn by the tubes is very closely a linear function of the grid-voltage swing. The associated output-circuit loading is adjusted so as to realize from the tube a maximum conversion efficiency. Some curves showing how plate-current efficiency varies with effective load impedance are shown in Fig. 55. The crest position on these curves depends upon the tube characteristics and the power factor of the circuit into which it operates. These curves were taken at a broadcast frequency by varying the load

upon the output circuit of a linear amplifier stage and measuring the efficiency of the stage at various d-c plate voltages.

Where the conversion efficiency is a linear function of the grid swing, the power output is necessarily proportional to the square of the grid swing. Hence the peak power output at 100 per cent modulation is four times that at which the modulation is zero. The steady power output under conditions of sustained 100 per cent modulation is 1.5 times the output of zero modulation. Therefore, in considering power-tube requirements for a class B linear stage, provision must be made with respect to filament emission and plate dissipation so that the tubes are capable of supplying peak power outputs of four times that of the nominal carrier-power output rating of the transmitter. This assumes that the modulation capability of the transmitter is 100 per cent.
FIG. 55. Load characteristics of push-pull 892 power-amplifier tubes.

In adjusting a push-pull linear amplifier, both sides of the circuit must necessarily have very nearly identical operating conditions with respect to grid swing and circuit adjustment, so that equal plate currents are measured on the individual tubes identified as *A* and *B* in Fig. 54. The grid-bias adjustment necessarily depends directly upon the plate voltage used since the position of the characteristic curve is moved with each corresponding change in plate voltage.

As illustrated in Fig. 54, with a simple triangular wave form, the method of determining optimum grid bias depends upon the point where an extension of the straight portion of the curve intersects the horizontal axis. Both dynamic curves of tubes *A* and *B* have their straight portions in direct alignment. Distortion due to the lower bend in each characteristic curve is averaged out together with the kva/kw inertia effect in the output-tank circuit. On the other hand for maximum modulation peaks with output increasing as the excitation voltage is increased, there is a limit to the output as represented by the upper bends, points S_1 and S_2, on the curves where the tube saturation points begin.

Linearity is therefore dependent upon grid bias, grid-exciting voltage, and output-tank loading. The procedure for setting taps for correct output-tank loading consists of first saturating the grids of the amplifier tubes with sufficient r-f grid driving power. Then with one-half normal class B r-f operating d-c plate voltage applied, the amplifier is loaded until it delivers rated carrier power normally to the antenna, the plate efficiency being usually between 65 and 70 per cent. Then the grid-exciting voltage is reduced (usually by means of grid-loading resistors) until the amplifier stage with full d-c plate voltage applied delivers the same rated carrier output with a corresponding plate efficiency of very nearly 35 per cent. This is the plate efficiency for a class B r-f amplifier as specified by Sec. 3.52 of the FCC rules in the determination of carrier out-

put power by the indirect method. Under this same section the plate efficiency for plate-modulated class C r-f operation of the last radio stage as measured by the indirect method is 70 per cent for transmitters having carrier power output up to 1 kw and 80 per cent for 5 kw and over.

55. High-efficiency linear-power amplifiers are a result of work to reduce the expense for operating power of broadcasting transmitters usually of 1-kw carrier output and above. The limitations of the class B r-f linear amplifier are such that, for satisfactory operation, the plate power efficiency ranges from 30 to 35 per cent. Considering the driver and modulator stages and the transmitter auxiliaries, with this system the over-all efficiency from power mains to carrier power output may range from 20 to 25 per cent. The high-efficiency amplifier circuit[1] provides a plate operating efficiency as high as 60 to 65 per cent to be realized from a linear-power amplifier.

FIG. 56. Block diagram of high-efficiency power amplifier.

The amplifier circuit (Fig. 56) has been divided in block form into individual units. The exciting voltage E_x passes into two branches. One leads into a negative 90-deg phase-shifting circuit, thus transforming it to the proper amplitude for grid excitation of the *carrier amplifier* tube. This voltage E_2 is amplified by the carrier tube, the a-c components of plate voltage becoming E_1 (180 deg out of phase with E_2). The output voltage E_1 in passing through the impedance-inverting network has its phase retarded an additional 90 deg at the output of the network. Therefore, in turning through 360 deg in this path, the resultant E_0 is in phase with the exciting voltage E_x. In the lower branch of the circuit the 180-deg phase reversal of E_x in passing through the grid network and the phase reversal produced in passing through the *peak amplifier* tube result in a correct phase of E_0 at the load. The phase shifts may be further clarified by the vector diagram of Fig. 57, where the output voltages produced by both the carrier and peak tube are illustrated as acting in phase to produce E_0 at the load.
FIG. 57. Phase relations in high-efficiency amplifier.

Figure 58 illustrates the theoretical individual and combined operation of the carrier and peak tube branches of the amplifier as produced by a modulated r-f voltage (assuming sinusoidal variation of r-f voltage with modulation). For the carrier amplifier the r-f plate voltage rises very nearly linearly over the region *O* to *A*, flattening off at this point owing to saturation; beyond this point any increase in exciting voltage for this tube produces practically no further increase in plate voltage. The carrier amplifier plate current on the other hand rises quite linearly from *O* to *B*. Thus from *O* to *A* the operation is quite similar to that of a class B r-f linear amplifier operating into a load impedance of constant value, whereas from *A* to *B* there is a progressive reduction in plate impedance under influence of positive delivery of power from the peak amplifier tube on upward modulation swing, as observed through the impedance-inverting network and the plate-current rises. The plate voltage of the peak amplifier tube rises linearly from *O* to *B*, where the curve flattens off because of saturation. This tube is biased to a point where little positive power is delivered for exciting voltages below carrier amplitude *A*. However, owing to coupling to the carrier amplifier tube output circuit through the impedance-inverting network, a voltage exists in its plate circuit during this idle stage for the tube. Therefore, a linear variation in plate voltage for the carrier amplifier tube between *O* and *A* causes a corresponding linear voltage variation between *O* and *A* in the plate circuit of the peak amplifier tube because it is

[1] Doherty, W. H., A New High Efficiency Linear Amplifier for Modulated Waves, *Proc. IRE*, September, 1936.

parallel with the load. Owing to grid-biasing conditions with respect to the excitation voltage for the peak amplifier tube, appreciable plate-current flow begins when exciting voltage assumes an amplitude greater than that necessary for an unmodulated carrier condition. Over the region *A* to *B*, plate current rises very nearly linearly to the limit at *B*. It is evident that at the crest of the modulation cycle corresponding to *B* both the carrier and peak amplifier branches are delivering equal power outputs in phase to the load.

Adjustments required for satisfactory operation consist of correct neutralization of the tube capacitance, correct grid biasing of carrier and peak amplifier tubes, adjustment of grid load resistors of both amplifier tubes and their grid and output tank circuits to resonance, as well as obtaining correct phase-inverting characteristics from the circuits involved. For correct loading of the amplifier, the r-f transmission line should be properly terminated to permit operation of the amplifier into a resistive load. It will be noted that for the purpose of securing the impedance-inverting characteristics required, a 90-deg phase shift is also secured. All other phase-shift networks are utilized to compensate for this undesired phase shift. Compensation for phase shift must be effective over all useful side-band frequencies and also at the carrier frequency. The 90-deg phase-shifting circuit in the grid of the carrier amplifier tube and the 180-deg phase-shifting circuit in the grid of the peak amplifier tube are utilized for compensation purposes only.

Fig. 58. Operating characteristics of high-efficiency amplifier.

56. Ampliphase Transmitter. Another method for increasing the efficiency of modulated transmitters is due to Chireix,[1] a modern version of which is produced by RCA under the name Ampliphase. Basically the system is one in which the r-f signal is phase-modulated by the a-f signal at low level, then amplified by high-gain class C amplifiers. The modulated signal is then converted to an a-m signal in the load. Simplified diagrams of this transmitter are shown in Fig. 59*b*.

The circuit functions as follows: A crystal oscillator is fed to two independent r-f channels through phase-shifting networks so that two r-f carriers are produced out of phase with each other by 135 deg. If the output from these r-f chains were 180 deg out of phase and were impressed on a common load, no power would be developed in the load. If, however, the phase is adjusted, say by the modulating signal, so that a 90-deg phase difference exists between the two carriers, then the load current will be approximately doubled, corresponding to a modulation peak, compared with the value with 135-deg phase difference. Therefore a 22.5-deg phase shift in each r-f channel will produce full modulation.

Following the oscillator, each r-f channel consists of a stage in which the phase is brought to the 135-deg value (Fig. 59*b*) by adjusting R_1. The output of this stage, the "d-c modulator," is fed to three modulated amplifiers in each of which the phase, for full modulation, is shifted 7.5 deg. This is accomplished in a circuit similar to the d-c modulator except that the phase shift is produced by a variable-resistance modulator tube as shown in Fig. 59*b*. Conventional amplifiers and frequency multipliers bring the final power to the required values.

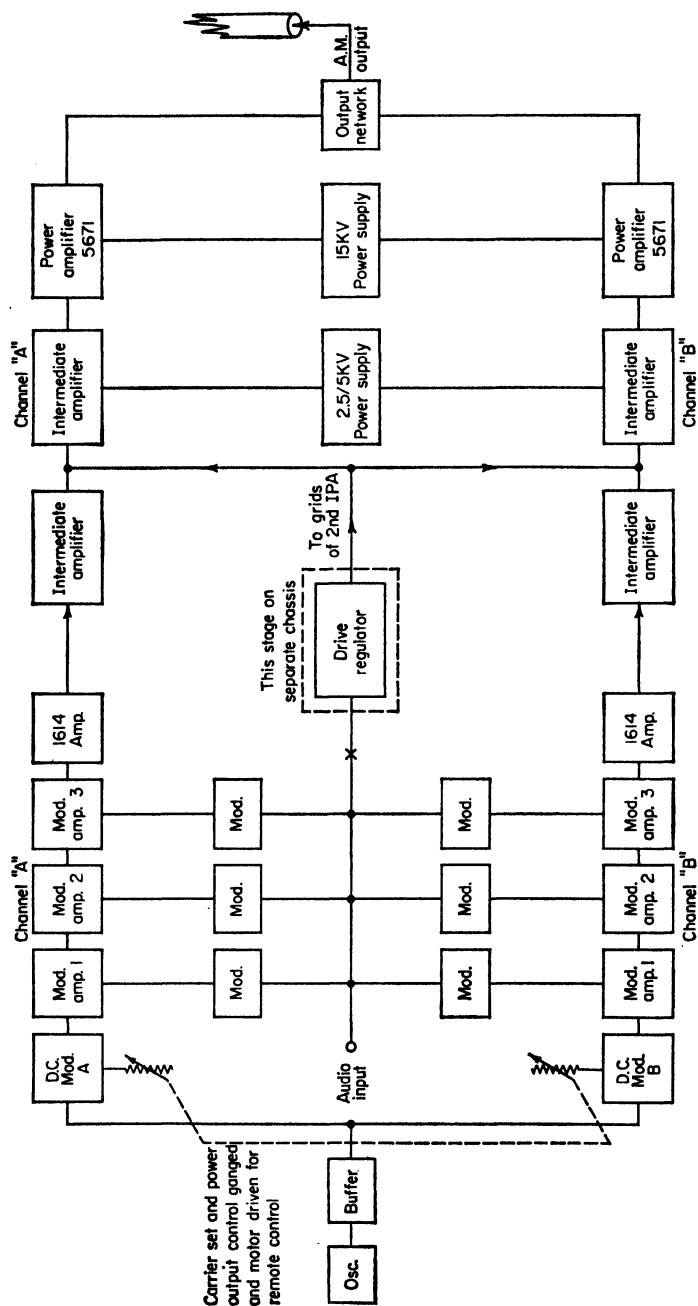
Because the final tubes must supply a load current that increases at modulation peaks, an increased driving voltage and increased bias are necessary to maintain the efficiency at full modulation. This is accomplished by a "drive regulator," a cathode-follower stage that samples the a-f signal, amplifies it, and applies it to the stage which drives the final.
[1] Chireix, H., High Power Outphasing Modulation, *Proc. IRE*, **23**, 1370, November, 1935. See also Starner, C. J., J. Q. Lawson, and C. D. Mulford, The RCA Ampliphase Fifty, *Broadcast News*, **84**, 54, August, 1955. See also Chap. 18, Sec. 37, of this handbook.


FIG. 59*a*. Block diagram of the Ampliphase transmitter. Only two high-power amplifier tubes are required compared to four in high-level design, two as r-f amplifiers and two as modulators.

Variable bias, controlled by the a-f signal, is applied to the driver to adjust the operating point. In this way about 80 per cent modulation of the driver provides 100 per cent modulation of the final.

The output circuit is a conventional pi network. About 6 db of feedback is supplied to the phase modulators to reduce the noise level and to iron out some nonlinearity in the over-all system.
FIG. 59*b*. Simplified circuits of the Ampliphase transmitter. (*Left*) D-c modulator (r-f amplifier) in which R_1 "sets" the carrier at the 135-deg value. Low-Q tank circuit with L and C chosen so that change in R_1 changes only phase and not impedance. (*Right*) Modulated r-f amplifier which is identical to the d-c modulator except that a tube serving as a variable resistance is substituted for R_1.
FIG. 60. Phase relations in Ampliphase transmitter.

57. Stabilized degenerative feedback as applied to broadcast transmitters reduces the harmonic distortion and noise created within the transmitter equipment, thus providing high-fidelity performance. Carrier-noise level may be as low as 65 db below 100 per cent modulation signal by utilizing degenerative feedback, even with a.c. applied to the filaments of all tubes. The FCC, Sec. 3.46, recommends that the carrier hum and extraneous noise (exclusive of microphone and studio noises) level (unweighted rss[1]) be at least 50 db below 100 per cent modulation for the frequency band of 150 to 5,000 cps and at least 40 db down outside this range. Harmonic distortion may be reduced to well below the FCC requirements, and in some cases the measured value of rms a-f harmonic distortion in the range 50 to 5,000 cps is less than 2 per cent at 85 per cent modulation and less than 3 per cent at 100 per cent modulation even with a high-efficiency power amplifier unit as a part of the system.

[1] Root sum square.

The application of feedback to the transmitter follows the same principles as applied to audio amplifiers. Application to radio transmitters is, in general, more complex than when applied to amplifiers.

In operating a transmitter with feedback the over-all gain of the audio system is reduced by the amount of feedback used. If 30 db of feedback is employed and the feedback voltage is removed suddenly by some fault, the program input will be 30 db too high, and readjustment of the program input level must be made instantaneously to prevent overloading.

With the application of feedback to cascade r-f amplifiers it becomes extremely difficult to maintain the phase of the rectified signal picked up at the output of the transmitter sufficiently close to the 180-deg rotation required throughout the entire a-f stage. Unless all networks in the entire cascade system are correctly designed, the kva/kw ratio of all r-f tank circuits is kept to a very low value, and stray capacitances are minimized, there is an accumulative phase shift through the feedback loop wherein the degenerative system is active.

Under conditions where the voltage fed back to the audio input of the transmitter after passing through the feedback loop is other than 180 deg out of phase with the input signal, less noise and distortion cancellation result. This is especially true under conditions where the phase shift of the feedback loop becomes less than 90 deg or more than 270 deg. At frequencies where the phase shift approaches zero and 360 deg from that of the input signal, stabilizing circuits are necessary to prevent violent oscillation of the entire transmitter, provided, of course, that the amplification around the loop is at least unity. These frequencies are sometimes referred to as those at which the phase "turns over." For the h-f turnover point, say around 25 kc, an adjustable stabilizing filter may be utilized in one of the low-power speech amplifier stages. This prevents oscillation of the transmitter at the particular high a.f. where the condition exists and for this reason it is called the *anti-sing* circuit. In addition there may be required an l-f (below 100 cps) stabilizing circuit in one of the low-power stages to prevent oscillation at the l.f. at which another unstable condition exists.

By correct proportioning of all constants of the a-f and r-f stages and associated networks throughout the entire section of the transmitter containing the feedback loop and by application of stabilization circuits together with careful transmitter adjustments, an effective amount of feedback can be secured for cancellation of noise and distortion.

MODULATION EQUIPMENT

58. Speech Amplifier. An audio amplifier employing power tubes is usually necessary as the preliminary part of the audio system of a transmitter to raise the audio signal to a sufficient amount to swing the grids of the modulator tubes. Resistance coupling is frequently used.

Amplitude modulation provides a means for reproducing a signal containing a distortion not exceeding a few per cent with the carrier fully modulated. In broadcasting transmitters it can be effected by either plate or grid modulation. When grid modulation is applied to a power tube, either by bias-voltage or r-f grid-voltage change, the efficiency of the power amplifier is rather low, ranging from 30 to 35 per cent. A plate-modulated radio stage operating as a class C amplifier has a comparatively high efficiency ranging from 70 to 80 per cent. This advantage of higher efficiency, however, is offset by the low efficiency of the plate modulator unless a class B audio amplifier is used for modulating. Therefore there is not much difference in the two systems, in so far as efficiency is concerned, with respect to power and vacuum-tube costs except under conditions where modulating power for a class C r-f output stage is supplied from a modulator of rather high efficiency.

When the power-amplifier stage of the transmitter is plate-modulated, the setup is called a *high-level system* of modulation, whereas a transmitter modulated in a low-power stage of the transmitter and followed by a class B r-f power amplifier is termed the *low-level system* of modulation.

59. Modulators and Modulated Amplifiers. In Fig. 61 is shown a constant-current system of modulation due to Heising.[1] The modulator and modulated amplifier are connected in parallel with a constant-current source of supply. This is connected to the common plate lead through a large inductance L_1 called the *modulation choke.*

The dynamic modulating characteristics can be determined with a fair degree of accuracy from the static characteristics of the modulator tubes in a method illustrated in Fig. 62. The modulated amplifier is assumed to be a pure resistance load in parallel
Fig. 61. Heising constant-current modulator and equivalent.

with the plate resistance of the modulator tubes and both assumed to be supplied with power through a modulation choke of infinite impedance. The sum of the instantaneous currents in the amplifier and modulator in this case is a constant. An approximation is made of the number of modulator tubes required to modulate a given r-f amplifier. The plate-current ordinate for a single tube must be multiplied by the number of modulator tubes before the load line BA can be plotted, the slope in amperes per volt which depends upon the load resistance produced by the amplifier. Line BA was chosen for two modulator tubes operating at 3,000 volts into an amplifier of 2,000 volts and 150 ma or an effective resistance of 13,333 ohms. The mean modulator plate current I_0 is chosen from allowable plate dissipation and load line BA drawn in about operating point C. The modulator grid voltage swings from the potential of the cathode to equal grid voltage on the other side of the operating point. By taking readings of plate current and voltage from end points of the load line, the following information becomes available:
Fig. 62. Method of determining modulator characteristics.

$$\text{Modulation factor} = \frac{E_A - E_B}{2E_0}$$

where E_A = max plate-voltage swing
E_B = min plate-voltage swing
E_0 = d-c plate voltage at operating point C

$$\text{Per cent second harmonic distortion} = \frac{\frac{1}{2}(I_A + I_B) - I_0}{I_B - I_A} \times 100$$

where I_A = max plate-current swing
I_B = min plate-current swing
I_0 = plate current at operating point C

$$\text{Power output in watts} = \tfrac{1}{8}(E_A - E_B)(I_B - I_A)$$

60. Design for High Audio Fidelity. In the design of the modulated amplifier of the above system certain elements must be properly proportioned to afford a uniform frequency characteristic. C_1 (Fig. 61) should be large enough so that its impedance at the lowest frequency to be transmitted is less than one-third of R_1, or the plate-dropping resistor.

C_2 provides an r-f path from plate to filament of the amplifier tube and at the same time breaks the d-c path. It must also break the path for higher-frequency a-f current and force it to flow through the r-f amplifier tube. It should, therefore, be no larger than necessary to conduct the r-f plate current without producing excessive phase shift in the plate current under conditions where C_2 is less than $2C_3$.

Sufficient impedance of the modulation choke over the a-f range is another important factor in circuit design. Its impedance at the lowest a.f. should be at least two times the effective resistance load produced by the r-f amplifier tube. The choke should be free from inherent self-capacitance defects over the frequency range to maintain a sufficiently uniform high impedance at the higher frequencies.

High-quality signal reproduction requires that amplitude distortion should be kept at a minimum. A common cause of distortion is underexcitation of the grid of a modulated amplifier tube when plate modulation is applied. This results in insufficient driving voltage during periods of high plate-voltage swing and consequently peak-output limiting. Trouble from this cause shows up quite clearly upon an amplitude curve or upon an oscillograph in the form of chopped-off positive peaks. In Fig. 63 are shown amplitude curves taken on the modulated carrier of a stage the grid of which was excited to saturation as shown in A and underexcited in B. It is a custom to have available a surplus of driving power for a modulated amplifier to prevent any possible occurrence of amplitude distortion.

FIG. 63. Amplitude curves taken on a modulated amplifier. Curve A taken on a stage with sufficient driving power to saturate the grid and showing negligible distortion. Curve B taken on stage with insufficient grid excitation to cover the positive peaks.

The constant-current or Heising system of plate modulation is often designated as a class A system, since the modulator tube performs under conditions similar to those encountered in a class A amplifier.

A properly designed class B system permits much higher plate efficiency to be secured from a given set of tubes and correspondingly a much greater output than with a class A system. This efficiency may reach as high as 66.6 per cent with a small percentage of audio harmonic distortion.

Inasmuch as it is often necessary to drive the grids of class B audio amplifiers into their positive grid-current region to obtain maximum power output, it is important for the driver-amplifier stage for the modulator stage to have a good output voltage regulation. This calls for driver tubes having a sufficient output capacity to deliver an undistorted voltage to the grids of the class B stage, even though there is a nonuniform increase of load on the driver stage caused by the class B tubes as they are driven through the positive grid-current region of their dynamic operating characteristics.

F-M SYSTEMS

The method of program signal transmission by means of f.m. utilizes a frequency variation or deviation at the audio rate, the deviation frequency being a small percentage of the unmodulated carrier frequency.

Assume the existence of an f-m transmitter operating on 90 Mc and that a maximum deviation of ±75 kc is desired. Then a sustained sine wave of, say, 1,000 cps may be applied to the modulator audio input, with the audio signal amplitude adjusted to provide ±75 kc deviation. This would result in utilizing the full modulation capabilities of the transmitter. With a complex wave program input, the frequency deviation at any instant corresponds to the amplitude of the complex wave at that instant.

Channels for f-m transmission have been assigned 200 kc apart, which has been found to be a sufficient carrier separation to allow a frequency deviation of as much as ±75 kc. The width of the band required[1] in the frequency spectrum is *at least* twice the value of the highest modulating frequency or twice the frequency deviation, whichever is greater. Important side-band components may occur outside these limits, however.

61. F-m Methods. There are diverse methods of producing f.m. on an r-f carrier. Two rather different systems have been classified as (1) direct f.m. and (2) indirect f.m., accomplished primarily by phase modulation.

Direct f.m. is produced by frequency-modulating directly the master oscillator stage, which has a normal unmodulated carrier frequency of either the transmitter output frequency or a convenient subharmonic thereof. In papers[2] giving a mathematical treatment of f.m., it has been illustrated that, if the tank circuit constants of the oscillator stage are varied in accordance with the audio-input frequencies, there will be produced a resultant f-m output signal. With some device operating as a condenser microphone varying the capacitance of the tank circuit of the master oscillator, there may be produced an r-f carrier frequency modulated to conform with the sound undulations vibrating the microphone diaphragm. This illustrates f.m. by the direct method.

A modified form[3] of the direct system of frequency-modulating a transmitter is accomplished through the use of a tube (Fig. 64), employed as a variable reactance. Here a variable reactance is caused to exist between the cathode and anode of the reactance tube by grid-bias variation at an audio rate. By supplying the grid of the reactance tube with r-f voltage previously passed through a phase-shifting circuit C_1R_1, the grid-excitation voltage is caused to be in phase quadrature with the plate voltage. Then the a-c portion of the reactance-tube plate current i_p will be very nearly

$$i_p = g_m e_g$$

However, since

$$e_g = jKe_p$$

then, under influence of the phase-shifting network,

$$i_p = jKg_m e_p$$

and

$$Z_p = \frac{e_p}{i_p} = -\frac{j}{Kg_m}$$

from which the equivalent capacitance produced by the tube is

$$C_e = \frac{Kg_m}{2\pi f}$$

The reactance tube may be caused to appear as an equivalent variable capacitance across the oscillator tank circuit.

62. Carrier Stabilization. For satisfactory transmission of the f-m signal it is essential that, in addition to producing the modulated wave, there must be a satisfactory carrier-wave stability. For this reason it is necessary to add a stabilizing circuit by which the average frequency of the carrier wave is compared to that of a precision crystal oscillator. The resulting difference frequency when applied to a special motor coupled to a tuning compensator provides carrier-frequency correction to the assigned channel frequency.

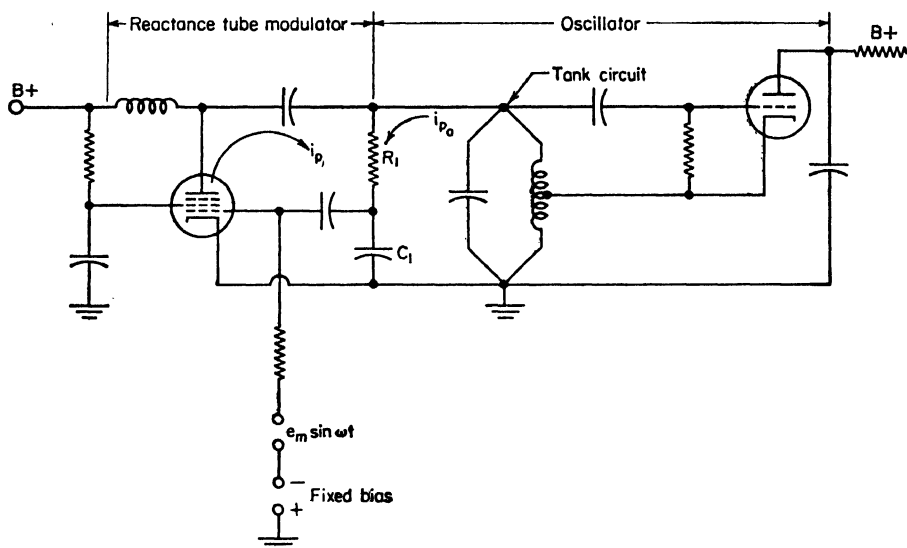
In Fig. 65 are shown the basic circuits for monitoring the transmitted carrier frequency within the required frequency tolerance. The system consists of two balanced


FIG. 64. Reactance-tube modulator.

modulators arranged to secure in the output of each a beat frequency equivalent to the difference between a crystal-frequency standard and that of the master oscillator. The output of the crystal oscillator is divided to feed equal amounts of energy to the two balanced modulators. Two phase-shifting networks provide a 90-deg phase displacement between the input signals applied to the two balanced modulators.

Since the signal from the master oscillator provides a signal of the same phase for both modulators, then the 90-deg phase displacement in crystal-oscillator output signals supplied to the modulators will provide a similar phase displacement in the beat-frequency output from the two modulators. In this manner two-phase energy is available for driving a tuning motor to compensate frequency shift of the master oscillator. The direction of rotation of the 90-deg vectors representing the signals at the outputs of the two balanced modulators changes from clockwise to counterclockwise depending upon whether the master-oscillator frequency is higher or lower than the crystal standard frequency.

The two-phase a-c output of the two modulators, therefore, has the characteristic of reversing one phase when the output secured from the master oscillator swings through zero beat from a higher to a lower frequency compared to the crystal.

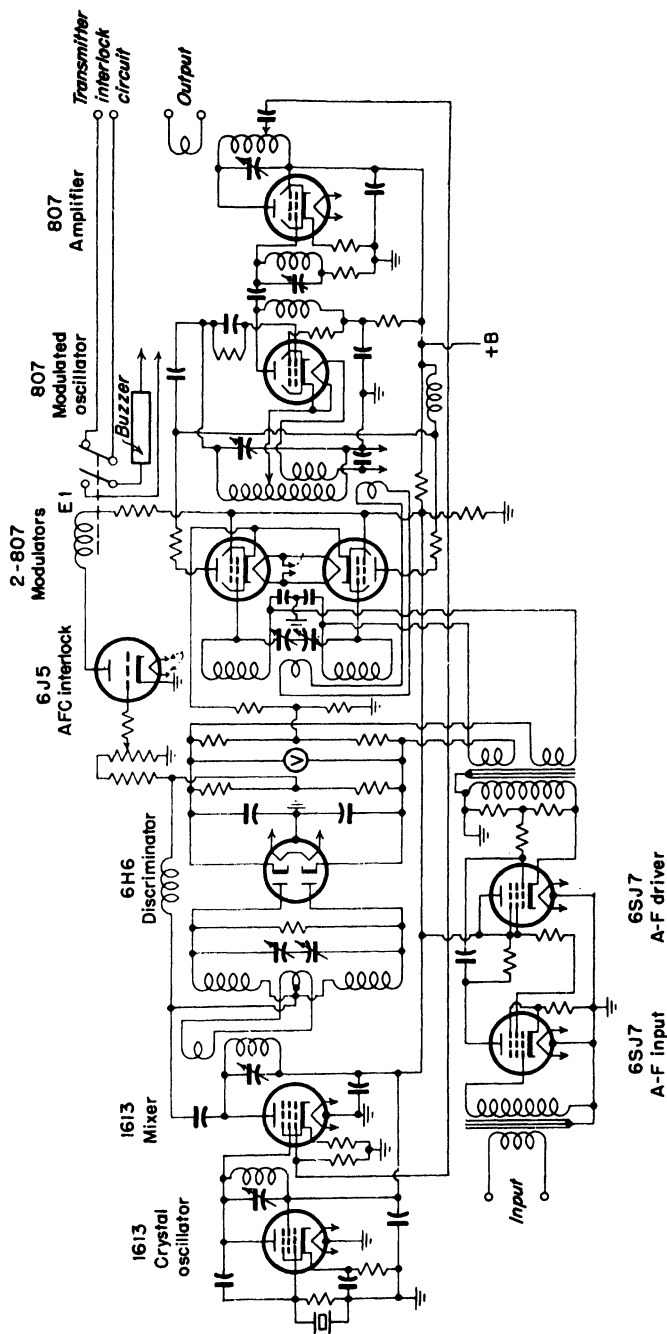
The two-phase a-c output of the two modulators thus secured may be used to energize the windings of a two-phase motor. If the master-oscillator frequency is higher than that of the crystal, the motor shaft will rotate clockwise and so on. A com-


Fig. 65. Complete f-m transmitter circuit producing a compensating voltage from a frequency deviation.
FIG. 66. Frequency-control f-m exciter.

pensating variable tuning capacitor may be attached to the motor shaft and employed to retune the master oscillator to zero beat with the crystal, which operates on a submultiple of the assigned carrier frequency.

Elements of the RCA BTF-3B reactance-tube modulator f-m system are shown in Fig. 66. The operating characteristics of this transmitter follow:

Frequency range	Any specified frequency between 88 and 108 Mc
Power output (into transmission line)	1,000-3,000 watts
R-f output impedance	35-75 ohms
Carrier-frequency stability, deviation less than	2,000 cps
Modulation capability	±100 kc
Method of modulation	Reactance tubes
Audio input impedance	600 ohms
Avg program level	+4 ± 2 vu
100% modulation level	+12 ± 2 dbm
A-f response*	
30-15,000 cps, uniform within	±1 db
A-f distortion†	
30-100 cps	1.5%
100-7,500 cps	1.0%
7,500-15,000 cps including all harmonics up to 30 kc at 75-kc swing	1.5%
F-m noise level, below ±75-kc swing†	65 db
A-m noise level, below 100% amplitude modulation†	50 db

* For preemphasized response the preemphasis filter is provided to be inserted in the 600-ohm audio-input line at the most effective point.

† Distortion and noise are measured following a standard deemphasis network.

The 1-kw Western Electric type 503B-2 f-m[1] transmitter utilizes reactance tubes directly as frequency modulators in a manner as shown in Fig. 67. The method used to maintain constant the mean carrier frequency is called "synchronous f.m." since it operates by comparing the mean frequency (measured in total carrier cps) of the f-m oscillator to a precision fixed-frequency standard. The difference frequency thus derived is then utilized as a control medium for mechanically retuning the oscillator stage, keeping the oscillator frequency an exact multiple of the standard.

Figure 68 shows the frequency-stabilizing system, which functions through a small portion of the 6-Mc f-m oscillator (assume a 96-Mc carrier), being fed back through frequency dividers to obtain a 6-kc frequency equal to that of the precision quartz-crystal frequency standard. The 6-kc frequency, a much lower submultiple of the 96-Mc carrier, is necessary to produce a difference frequency sufficiently low to be within the range of the rotating magnetic field of the electric motor used for retuning

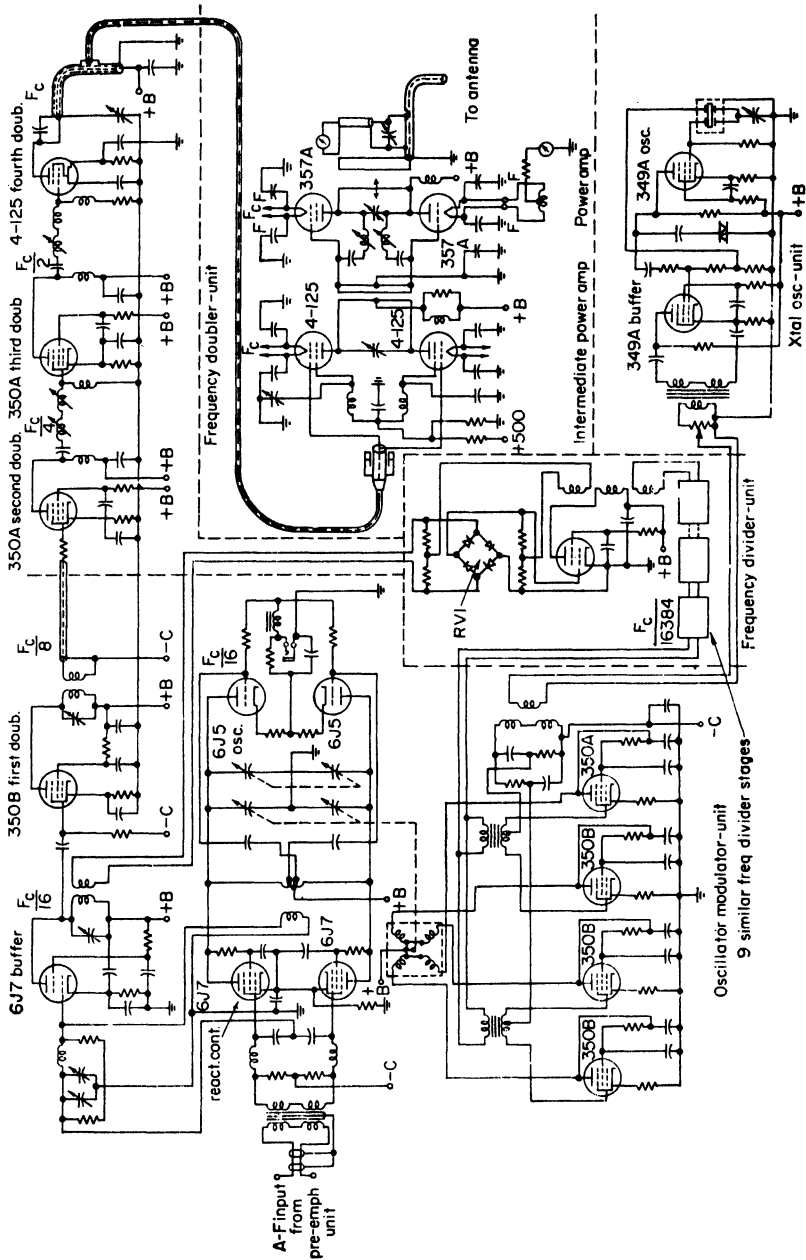
[1] Ganzenhuber, J. H., Western Electric FM Broadcast Transmitters, *FM & Television*, September and October, 1946.


FIG. 67. Essential circuits of the 1-kw Western Electric f-m transmitter.

the oscillator variable capacitors through a suitable speed-reduction mechanism of gear trains. The direction of rotation of the motor depends upon whether the oscillator frequency is higher or lower than the fixed multiple frequency of the standard. Thus automatic readjustment of the oscillator tuning is made in the correct direction so that when exact synchronism occurs between the frequency fed back from the f-m oscillator and the frequency standard the motor is at rest.

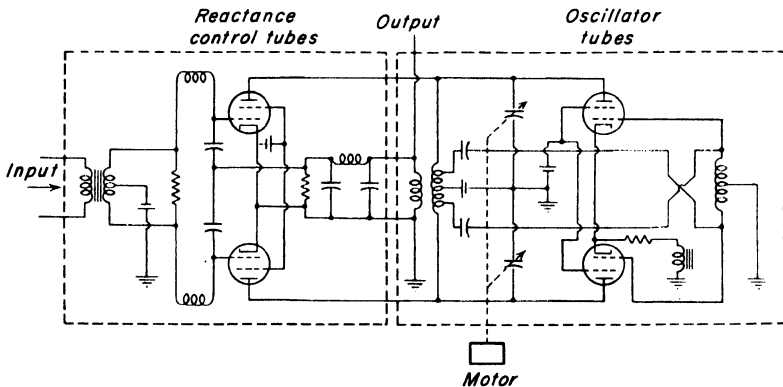
Because of the inertia of the motor rotating elements and the high order of frequency division used, the motor is not caused to rotate by frequency deviations produced on
FIG. 68. Frequency-stabilizing system of Western Electric.


FIG. 69. Reactance-tube circuit of Western Electric f-m transmitter.

the carrier at an audio rate during modulation. The main advantage claimed for the synchronized f-m method is that the output frequency is maintained identical in precision to the standard by making all the controlling factors in terms of frequency.

63. Armstrong F-m Method. The indirect or p-m method of producing f.m.[1] consists in general of a constant-frequency oscillator, a modulator (the function of which is to change the phase of the oscillator output as illustrated in Fig. 70), and a series of multipliers to increase the amount of p.m. sufficiently to secure the frequency shift or modulation required in the radiated signal. Results are secured by splitting the oscillator output into two paths. One path contains a phase-shifting network which

[1] Armstrong, E. H., A Method of Reducing Disturbances in Radio Signaling by a System of Frequency Modulation, *Proc. IRE*, May, 1936.

shifts the phase 90 deg and the other a balanced modulator generating side bands with a suppressed carrier.

A combination of these two signals produces a p-m signal with a phase-shift modulation capability up to ±30 deg with satisfactory linearity. An f-m wave is derived therefrom by transmitting the signal through frequency multipliers. A multiplication of several thousand times is required to obtain deviations of ±75 kc.

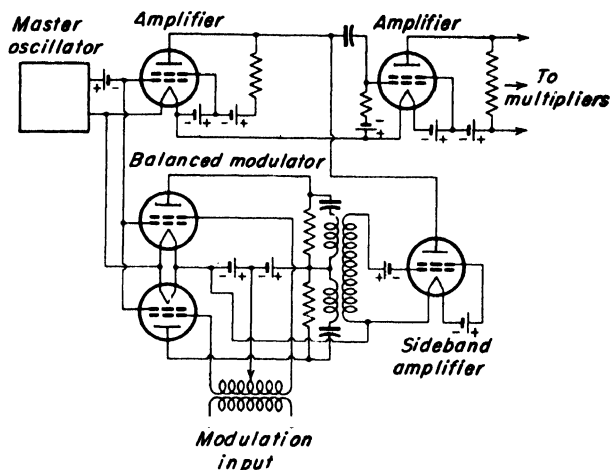
To produce f.m. and at the same time maintain a constant deviation frequency, the p.m. must necessarily be inversely proportional to the modulating frequency. Therefore with this method it becomes necessary to have the amplitude of the p-m signal decrease in proportion to the frequency of the audio input to secure a flat a-f transmitter response. This is usually accomplished by a corrective network in the audio circuits ahead of the modulator.


FIG. 70. Armstrong frequency modulator.

The amount of frequency multiplication required following the production of phase modulation to secure the desired f.m. by the indirect method depends upon (1) the amount of p.m. produced by the modulator, (2) the lowest a.f. transmitted, and (3) the deviation or frequency swing at the output frequency. For a phase shift of 0.5 radian, frequency deviation of ± 60 kc, and lowest a.f. of 30 cps, the frequency multiplication required is 4,000 times.

To obtain this amount of frequency multiplication, the initial oscillator frequency must be multiplied in several stages, then heterodyned down to a lower frequency, and again multiplied a number of times to secure the output frequency.

64. Merits of F.M. vs. A.M. With the application of f.m. to transmitters operating in the v-h-f band, the relative merit for this system of signal transmission can be evaluated on the basis of an a-m system. The v-h-f signal field intensity[1] at a given distance from a particular transmitting antenna may be determined from theoretical and empirical relationships[2] and derived from extensive mathematical and experimental work. Actual experimental tests[3] have shown that an interfering audio signal (output of receiver) will create objectionable interference if its level is about 30 to 40 db below the desired signal. Thus service areas can be defined as zones in which the desired component of the resulting audio signal is at least 35 db above

[1] Trevor and Carter, Notes on Propagation of Waves below Ten Meters, *Proc. IRE*, March, 1933.

[2] Devino and Hunt, Ultra Short Wave Propagation over Land Burrows, *Proc. IRE*, December, 1935

[3] Weir, I. R., Field Tests of Frequency and Amplitude Modulation with U-h-f Waves, *Gen. Elec. Rev*, May, 1939; Crosby, M. G., The Service Range of Frequency Modulation, *RCA Rev.*, January, 1940; Guy, R. F., and R. M. Morris, NBC Frequency Modulation Field Tests, *RCA Rev.*, October, 1940.

the interference. For very-high-quality reproduction, this figure runs from 40 to 55 db.

For interfering signals on the same channel as the desired signal, it is evident that, if a.m. is used, a signal input ratio of 35 db is required to secure the desired output ratio. However, in f.m. the ratio of signals at the receiver input needs to be only about 6 db since the receiver for f-m reception responds to frequency variations and limits amplitude variations such as those caused by noise and undesired signals.

On this basis there are advantages of f.m. over a.m. because of (1) improved signal-plus-noise to noise ratio. Experimental results have shown this difference to be as much as 25 db as influenced by intensities of automobile ignition, X rays, and other man-made interference. Atmospheric interference being small at v.h.f., it becomes negligible in comparison with man-made interference. (2) A uniform and definite service area from a given transmitter since f-m signal-plus-noise to noise ratio remains high until field intensity reaches a low value. (3) A smaller geographical interference area obtained when two f-m transmitters are operated simultaneously on the same frequency as compared to similar operation of two a-m transmitters. (4) An r-f amplifier used to increase an f-m signal is more efficient than one used for a.m. because f.m. can be accomplished at low level followed by a class C r-f power amplifier. (5) For a given service area, less radiated power is required for f.m. because of the improvement in signal-plus-noise to noise ratio obtained with f.m. (6) For a given power output, power-tube operating costs are less because relatively smaller tubes can be used for f.m. for a given power output.

The FCC has provided for 65 channels each 200 kc wide for f-m carrier frequency assignments between 88 and 108 Mc.

Preemphasis. A-f preemphasis at the transmitter is added as a means of increasing the effective modulation at the higher audio frequencies since, for average programs, the peak levels of modulation at these frequencies are lower than for the lower frequencies. At the receiver a corresponding amount of deemphasis is employed to bring the modulation back to its proper level. In this manner an increase in the signal-to-noise ratio is brought about.

Preemphasis is effective only when the inherent noise level of the transmitter at the point of preemphasis is low, since any noise or higher frequency disturbances already existing would be emphasized along with the microphone modulation. Since f-m transmitters generally have less noise (as required by the FCC) than a-m transmitters, this form of enhancing the higher audio frequencies is more effective with f.m. than with a.m.

Preemphasis is generally expressed in terms of the time constant of an *LR* circuit which produces the effect. The required value is that corresponding to a time constant of 75 μsec.

An important advantage of the f-m transmitter over one utilizing the amplitude system lies in the fact that the efficiency of the r-f amplifier stages can be as great as it is for class C telegraph service. At v.h.f. this may be between 50 and 70 per cent.

Transmitter Measurements. The measuring equipment is considerably different than is required for an a-m station since there is a variation in frequency of the emitted wave with modulation while the amplitude is kept more or less constant. This is exactly the reverse of a.m., where the carrier is varied in amplitude but maintained at a constant frequency. The frequency swing or deviation can be measured by applying sustained tone to the transmitter and then measuring the relative intensities of the carrier and the side frequencies present, the relative amplitudes of which correspond to the Bessel functions involved.[1]

TRANSMITTER DETAILS

65. Air- and Water-cooled Tubes. For tubes of low power, artificial cooling during operation is usually not necessary, radiation into the air being sufficient. For the larger tubes, however, artificial cooling is usually accomplished by means of a circulat-

[1] Crosby, M. G., A Method of Measuring Frequency Deviation, *RCA Rev.*, April, 1940.

ing-water system which causes a sheet of water to pass over the anode surface at very high velocity.

To restrict leakage of current from the anodes to the grounded pipes of the water system, connection is made between the anodes and the water system through a long length of coiled hose or porcelain tubing. This interposes, between the anode and ground, columns of water long enough to make the electrical resistance to ground very high; as much as 100 ft of coiled hose may be used, giving resistances of 0.5 up to several megohms.

In many cases distilled water is used, the water being maintained at a satisfactory temperature by an artificial cooler, since for economical reasons it is desirable that the same water be used indefinitely.

The water-cooling and circulating system is automatically started when the transmitter is turned on, and the transmitter is automatically turned off in the event of any failure in the water-cooling system. One method of doing this employs a Venturi tube whose inlet and output orifices are connected to a device operated by the difference in pressure established between the two orifices by the flow of water. If the flow is interrupted or falls below its normal value, a contactor through additional relays causes the power supply to be disconnected.

Sometimes a milliammeter is provided on the transmitter panel which indicates the magnitude of the current leaking through one of the closed coils, the amount of current serving to indicate the relative purity of the water and indicating when it is advisable to change the water supply.

In place of water cooling, forced-air cooling is also used on some large tubes. For the large dissipation required, a large number of radiating fins are made a part of a copper radiator attached to the copper anode. Sufficient air is forced upward and between the cooling fins to carry away the heat developed on the anode. Because of the high electrostatic capacitance created by these anodes, they are not used on the very high frequencies with transmitters of very high power.

66. Power Supply. Plate-voltage supply for transmitters may be obtained from d-c generators, high-vacuum tube rectifiers, mercury-arc rectifiers, or hot-cathode mercury-vapor rectifiers.

Table 2. Comparison of High-vacuum and Mercury-vapor Tube Rectifiers*

No. of tubes	Tube type	Circuit	D-c output			Tube drop		Losses, kw		Efficiency, per cent
			Volts	Amp	Kw	Volts	At amp	Filament	Tube drop	
6	UV-214	3ϕ, double-Y	15,000	12	180	1,560	6	6.9	18.7	85.7
6	UV-857	3ϕ, full-wave	15,000	12	180	15	12	1.5	0.36	98.8
6†	UV-857	3ϕ, full-wave	21,000	30	630	15	30	1.5	0.9	99.4

* *Proc. IRE*, **18** (1), January, 1930.
† Maximum rating.

The hot-cathode mercury-vapor rectifier is considered the best method of supplying high voltages to transmitter plate circuits. The most striking difference between mercury-vapor tubes and high-vacuum tubes is the internal voltage drop between plate and cathode. In the high-vacuum tube the voltage drop may vary from a few volts to several thousand volts, depending upon the current, element spacing, etc. In the mercury-vapor tube the space charge is limited by the arc drop of the vapor which is practically constant at values between 12 and 17 volts regardless of the current.

Table 2 gives a direct comparison of the relative efficiencies of a high-vacuum tube and a mercury-vapor tube. Note that the mercury-vapor tubes give very low internal voltage drop and have considerably higher efficiencies.

Two fundamental limits determine the power output that can be obtained from any number of tubes operated in any type of circuit: (1) the maximum peak inverse voltage at which the tube can operate without flashing back and (2) the maximum peak plate current which the cathode can supply with a reasonably long life.

The maximum peak inverse voltage which can exist across a tube in any of the usual types of circuits is equal to the line-to-line peak or crest voltage of the power transformer less the voltage drop of the conducting tube.

The peak plate current depends upon the type of circuit, tube, filter, and load. In a single-phase full-wave circuit each tube must carry the full-load current for half the time. In the three-phase half- and full-wave circuit each tube carries the load current for one-third of the time. If the rectifier feeds into an inductance, square blocks of current are drawn from the rectifier and the peak plate current approaches the d-c value. If the rectifier feeds into a capacitance load, plate current is drawn for only a part of each half cycle and the peak current may reach values of from three to five times that of the d-c load current.

Table 3. Hot-cathode Mercury-vapor Tube Ratings

Tube type	Filament		Peak inverse voltage	Peak anode current, amp
	Volts	Amp		
866A	2.5	5	10,000	1.0
872A	5	7.5	10,000	5.0
869B	5	18	20,000	10.0
857B	5	30	22,000	40.0

Table 3 gives data on several typical hot-cathode mercury-vapor tubes designed for radio-power-supply purposes. Single-phase full-wave and three-phase half-wave circuits are quite generally used. The three-phase full-wave circuit is particularly applicable to the half-wave mercury-vapor tube, since it gives a peak inverse voltage whose magnitude is only 4.5 per cent greater than the average output voltage; the wave form is that of a six-phase rectifier.

FIG. 71. Class B r-f amplifier arranged for parasitic suppression.

67. Parasitic Oscillations. One of the most important design features of a transmitter is to provide for adequate suppression of parasitic oscillations. Such spurious oscillations are usually caused by regeneration in an amplifier stage. They have frequencies different from the fundamental or its harmonics.

All classes of amplifiers are subject to these oscillations. Suppressing them in a class C amplifier is not usually so difficult as in the class B types, where the grids of the tubes are driven positive for a considerable portion of the cycle. Before reliable and economical service can be realized from a transmitter of any type, all tendencies for parasitic oscillation must be suppressed to prevent serious lessening in the life of vacuum tubes or program interruptions because of arc-overs in the transmitter. Such oscillations may exist in an otherwise normal amplifier stage and may not be evident to casual inspection owing to their disappearance entirely when grid excitation is removed.

A typical class B r-f power-amplifier stage is shown in Fig. 71. This amplifier con-

tains inherent design features which have a tendency to suppress spurious oscillations. C_6 and C_7 assist by acting as a very low reactance path for all parasitics of a frequency higher than the fundamental with a result that they effectively load the parasitic circuit. Connections between these capacitors and the tube grids are kept at an absolute minimum. Loading resistors R_1 and R_2, the real purpose of which is to improve the regulation of the grid circuit as the grids swing positive, also act as a resistor load to damp out oscillations. C_8 and C_9, with their mid-point grounded, act as low-reactance paths to ground for frequencies above the fundamental.

The frequency of parasitic oscillations may be anything from the very low end of the frequency spectrum to the u-h-f region. Parasitics of very low frequencies, in the neighborhood of less than 1 to 10 cps, are sometimes set up by the dynatron action of the tubes at the natural period of the power-supply filter circuit C_1, C_2, and L_1.

FIG. 72. Typical saturation curve of class B r-f linear amplifier showing dynatron effect of power-tube grids with E_b and E_c constant.

The existence of these low-frequency parasitics usually becomes apparent in the form of a severe irregularity in the saturation curve of the linear amplifier. Such a curve is shown in Fig. 72. The point X shows the beginning of this parasitic condition and Y the point where it ceases. It is caused by the dynatron characteristics of the amplifier tube grids and occurs at a point on their operating characteristic just before they are driven positive. A solution for such a condition is to use tubes whose amplification factor is such that the region XY falls below the carrier operating point. For this reason high-mu tubes have on some occasions been found to be more satisfactory than low-mu tubes.

FIG. 73. Equivalent parasitic circuit of Fig. 71.

Low-frequency oscillations of approximately one-third to one-fifth of the fundamental frequency are sometimes caused by tuned-grid tuned-plate regeneration with the plate chokes L_5 and L_4 in combination with C_{10} and C_{11} forming an output tank circuit. A similar grid tank circuit is formed by C_6, C_7, and L_3. Inasmuch as all tubes are effectively in parallel for this combination, the neutralizing capacitors tend to aggravate the condition rather than to prevent it. In Fig. 73 is shown an equivalent parasitic circuit of the combination as formed from the circuit in Fig. 71. The remedy is to change the values of L and C in either the parasitic grid or plate circuits so as to cause their natural periods to depart substantially from a near resonance condition. It is usually possible to suppress such oscillation by tuning the parasitic grid circuit to a higher frequency than the corresponding plate circuit.

The existence of these oscillations may usually be detected by applying excitation at the fundamental frequency to a stage with reduced plate voltage and grid-bias voltage until the tubes draw plate current. If oscillation of the stage continues after
fundamental grid excitation is removed, as indicated by neon lamps attached to the tube plates, the frequency of the parasitic may be determined by means of a wavemeter, and thus steps can be taken to eliminate it.

Oscillations within an amplifier stage at frequencies near the fundamental are usually caused by regeneration within an amplifier stage due to improper neutralization causing tuned-grid tuned-plate circuit oscillations. Improper circuit design or too close coupling between the inductances of the input and output circuits or chokes is also liable to cause this condition.

Parasitics of frequencies in the neighborhood of from 5 to 20 times the fundamental result in cases where the leads from the tube grids and C_6 and C_7 form a grid tank circuit, the resonance frequency of which is determined by various distributed capacitances and the inductance of the leads. Oscillations are made possible by the existence of a similar plate tank circuit formed by leads from the tube plates to C_8 and C_9 together with various stray capacitances. This form of parasitic is seldom sustained but shows itself most prominently when the stage is subject to high peaks of modulation. The trouble may usually be corrected by choke coils L_7 and L_8 inserted in the plate leads at a point adjacent to the tube plates.

These coils L_7 and L_8 together with a shortening of grid leads to an absolute minimum may also assist in suppressing oscillations of ultrahigh frequencies in amplifier stages employing two tubes in parallel. The grid leads of the two tubes, although connected, may combine with stray capacitance, thus forming a push-pull v-h-f oscillation. Such oscillations cause high r-f voltages to build up which may result in serious arc-overs from various parts of the tube output circuits.

68. Suppression of R-f Harmonics. It is the inherent characteristic of a vacuum tube, while functioning at a reasonably high efficiency as an amplifier, to generate harmonic frequencies of the fundamental. A station on 600 kc, if second and third harmonics were not suppressed, would produce interference with other stations on 1,200 and 1,800 kc. Field intensity measurements about a station are necessary to determine how much harmonic energy is radiated and to show the progress of work done toward reducing radiation.

In specifying the allowable harmonic radiation from a broadcasting station the IRE Committee on Broadcasting as of January, 1930, recommended that the maximum radio field intensity of a harmonic component measured at a distance of 1 mile from a station should not exceed 0.05 per cent of the field intensity of the fundamental. The FCC regulations prohibit radiation of a spurious or harmonic nature which may cause interference.

A field strength of, say, 500 μv per m at a distance of 1 mile was recommended as a maximum allowable intensity from a high-powered station. If in the case of a 50-kw station a circular-field pattern and equal attenuation are assumed for both a harmonic and the fundamental in the immediate vicinity of the station, a field strength of 500 μv at 1 mile would correspond to approximately 7 mw of radiated power at a harmonic frequency. The effect of directivity (illustrated in curve B, Fig. 74) may cause a field intensity of a number of times the value of 500 μv to be projected in a given direction with a very small fraction of 1 watt of harmonic power in the transmission-line and antenna circuits. Such a concentration of radiated power may form very objectionable interference. Considering the factors involved, therefore, it is evident that harmonic suppression must be attacked from a number of angles. These may be briefly outlined as follows:

1. Design of the transmitter circuits to reduce the harmonic content of the power delivered to the antenna circuits to a minimum.
2. Thorough and effective shielding of the entire transmitter or building.
3. Effectively grounding all harmonic drain circuits and elimination of long conductors near the transmitter coupled to it inductively or capacitively.
4. Reduction of directivity of harmonic radiation to a minimum.
5. Installation of shielded band- or low-pass filters at the input end of the transmission line to the antenna.

6. **Installation of an electrostatic shield between the power output stage and the antenna coupling circuits.**

Some commonly used triode circuits are shown in Figs. 75 and 76. The push-pull amplifier is superior to the single-ended circuit, as it is capable of producing a sum plate current of the two tubes which is symmetrical in wave shape and, therefore, it contains no even harmonics. Individual plate currents, of course, contain even
FIG. 74. Radio field-intensity survey. Dashed curve gives fundamental frequency field strength; B and C are second-harmonic intensity before and after reduction.
FIG. 75. Push-pull amplifier with high-kva tank circuit in transmission line.

harmonics which are drained to ground through C_3 and C_4, resulting in identical instantaneous even-harmonic potentials on each side of the tank primary but no actual even-harmonic current through it. Under these conditions an electrostatically shielded inductive coupling is provided to permit transfer of only fundamental and odd harmonics to the coupled circuit. For a condition of symmetrical plate current the tube characteristics must match closely, $C_1 = C_2$ and $C_3 = C_4$. The neutralizing bridge

must be balanced not only for the fundamental frequency but for even harmonics. This requires that the internal capacitances of the tubes should match. As will be shown later, a high ratio of circulating kilovolt-amperes in the tank circuit to the kilowatts delivered from the amplifier reduces the output of harmonics from a single-ended amplifier to a very low value. This is also true in the push-pull circuit.
FIG. 76. Line termination effecting reduced harmonic radiation.

The circuit shown in Fig. 76 will give a very small amount of harmonic output by proper design of the circuit constants. The curves in Fig. 78 show the filtering effect of a high kilovolt-ampere tank circuit in suppressing harmonic components of current generated in the tube. These curves show actual harmonic transferred to a given load circuit Z_L with a constant output at the fundamental and various kilovolt-ampere-to-kilowatt ratios of L_2 and C_2. Figure 77 shows improvement in tank circuits so as to increase the normal filtering action of an ordinary tank circuit. A high kva/kw ratio applied to these circuits is capable of reducing harmonic output to an extremely small amount. There are some limitations to the amount of filtering which can be secured by a high-kva tank circuit, however, since the I^2R losses in the circuit increase in proportion to the circulating kva and the cost of apparatus for increasing kilovolt-amperes in a circuit without increasing losses is considerable. In broadcasting transmitters there is the limitation of too low a decrement in a circuit attenuating too greatly the high frequencies of a modulated envelope. In Fig. 77*b* L_3C_3 is tuned to a particular harmonic to be eliminated. The use of antiresonant circuits (parallel traps) in the plate lead of an amplifier, while reducing to some extent a single harmonic, has a tendency to allow considerable voltage to build up at others. Most satisfactory results are usually secured by designing a minimum-impedance path for harmonics to ground as compared with a given high impedance at the fundamental.

FIG. 77. Improved tank circuits for suppressing harmonics.

FIG. 78. Effectiveness of high kva/kw ratio in reducing harmonic output with constant power output at the fundamental.

The effectiveness of the shielding may be determined by operating the transmitter

with full power output into a shielded phantom antenna. Measurement of the harmonic field strengths produced from the transmitter itself is direct evidence of how well it is shielded. Such radiation can usually be traced to a long conductor near the transmitter, coupled to it capacitively or through a common ground return. Ground conductors serving to drain harmonic frequency power to ground therefore should be as direct as possible and should not be extended so as to have a free end which might attain a high potential at resonant frequencies. This is particularly true of the harmonic drains near the antenna itself. These should have a separate ground to prevent coupling of harmonic frequencies into the antenna.

A sensitive wavemeter is very useful in determining the relative harmonic field intensities near the various circuits of a transmitter. When tuned to the frequencies of various harmonics and coupled to various circuits of the transmitter or placed at positions along nearby open conductors, this instrument will indicate proportionate amounts of the harmonic components of the current flow. By effectively grounding a long open conductor, either directly or through large capacitors at a number of distributed points, harmonic radiation can usually be eliminated.

The push-pull amplifier coupled to a long transmission line has often become a source of undesirable even-harmonic radiation because of sufficient electrostatic capacitance existing between the coupled circuits to permit a transfer of energy from the amplifier output circuit to the line. Unless this capacitance is reduced to an extremely low value, *e.g.*, by installation of a well-grounded electrostatic screen between the two coils, even harmonics usually find a path along the transmission line with a ground return to the generating source. An unshielded transmission line serves in this case as an effective directive radiator in the form of a large loop. Its effective height will be dependent upon the height of the transmission line above ground. Parallel flow of even-harmonic currents along the line, therefore, makes it a much more effective radiator in some directions than the push-pull flow of harmonic currents in the line.

A circuit very effective in reducing both the parallel as well as the push-pull flow of harmonic currents in a transmission line is shown in Fig. 75 in the form of a high-kva floating tank circuit $L_3C_9C_{10}$ tuned to the fundamental component of current flowing in the line. This tank circuit, while offering an impedance to the fundamental approaching an infinitely high value, offers a relatively low-impedance path to ground for the parallel flow of even harmonics equivalent to

$$Z_{ne} = \frac{-1}{4\pi f_{ne}C_9} = \frac{-1}{4\pi_{ne}C_{10}}$$

where resistance of circuit is negligible, Z_{ne} = impedance to nth even harmonic, and f_{ne} = frequency of nth even harmonic, and for the push-pull flow of odd harmonics between transmission-line conductors

$$Z_{no} = \frac{-2\pi f_{no}L_3}{(2\pi f_{no})^2L_3C - 1}$$

where resistance of circuit is negligible, Z_{no} = impedance to nth odd harmonic, f_{no} = frequency of nth odd harmonic, and $C = C_9/2 = C_{10}/2$, where $C_9 = C_{10}$.

As C_9 and C_{10} are increased in value the effectiveness of the circuit in reducing harmonics is increased. Since the transmission-line termination impedance is usually made to match the line impedance for the fundamental frequency, it usually happens that the line impedance is matched for this frequency only and as a result harmonic components of current and voltage in the line appear as standing waves along the line. In such a case the above tank circuit is most effective for eliminating a particular harmonic if it is placed at a point along the line of maximum voltage. This circuit alone was effective in one case in reducing second-harmonic radiation from a station to one-fifth of its former value.

Antiresonant circuits installed in a transmission line at current antinodes have been found very effective in reducing a single harmonic to which they were tuned. Extreme
FIG. 79. Low-pass r-f filter combined with antiresonant circuits in transmission line.

care should be taken in shielding these antiresonant circuits to secure best results. A combination of antiresonant circuits and a low-pass filter is shown in Fig. 79. This combination has been used successfully in severe cases of harmonic radiation from a very long transmission-line and antenna system. The filter matches the surge impedance of the line and has a cutoff frequency between the fundamental and
FIG. 80. Impedance of parallel and concentric-tube lines.

second harmonic. Antiresonant circuits have been found useful to sharpen the cutoff so as to attenuate sufficiently the second-harmonic frequency. Considerable experience in filter design and adjustment is required to secure optimum results from such an arrangement. For use with concentric lines with the outer sheath grounded, the filter shown in Fig. 79 is simplified to the extent of one-half, *i.e.*, one line to ground.

Methods of line termination shown in Figs. 75 and 76 are effective in reducing the possibility of harmonics reaching the antenna circuit. The termination shown in Fig. 76 may be improved by use of a multisection low-pass filter.

69. Antenna Circuit Termination for R-f Lines. Considerable improvement in antenna efficiency can be secured from an antenna located at some distance from the station so as to approach the ideal case of an antenna radiating in free space. An r-f transmission line is used for conveying the energy from the transmitter to the antenna. A simple form of such a line is
FIG. 81. Circuit for measuring impedance of transmission line.

the parallel two-conductor type, each conductor having a diameter of approximately ½ in. The spacing of the conductors is normally 12 to 15 in.

The curves of Fig. 80 show the characteristic impedance values with respect to spacing and conductor size of both the parallel-conductor-line and the concentric-tube type.

70. Transmission-line Calculations. There are diverse methods of measuring the characteristic impedance of a transmission line. A simple but effective method is illustrated in Fig. 81. With the setup shown and the switch thrown to the line position, a trial value of resistance R_2 is inserted. C is adjusted for maximum I_2. Then with switch thrown in the opposite position and R_1 set to equal R_2, C is adjusted
Fig. 82. Terminations for transmission lines.
Fig. 83. Termination for transmission line with one side grounded.
Fig. 84. Balanced transmission-line termination.

for maximum I_1. By trial, a combination may be found where there is a maximum value of I_1 and I_2 for the same setting of C with R_1 equal to R_2. This value of R_1 is the characteristic or surge impedance of the line.

When r-f power is transmitted over a transmission line to an antenna load, the line termination may be adjusted to afford a condition where there are no wave reflections by making the effective resistance of the termination equal to the characteristic impedance of the line. Several circuits used for terminating transmission lines are shown in Figs. 82 to 84 together with their equivalent circuits.

A formula for calculating the value of C_B for an effective resistance value Z_0 equal to the characteristic impedance of a two-conductor transmission line balanced to ground as shown in Fig. 82 as well as for a transmission line having one conductor grounded is as follows:

Let Z_0 = effective resistance of transmission-line termination
R_a = antenna resistance consisting of radiation resistance plus equivalent loss resistance
L_T = combined inductance-balance coils plus equivalent antenna inductance
C_A = equivalent antenna capacitance
C_B = line-termination capacitance
X_1 = reactance of C_B

X_2 = reactance of $X_L - X_{CA}$
Z_1 = impedance branch 1 = $-jX_1$
Z_2 = impedance branch 2 = $R_a + jX_2$

$$Z_0 = \frac{R_a X_1^2 - j(X_2^2 - X_1 X_2 + R_a^2)}{R_a^2 + (X_2 - X_1)^2}$$

$$C_B = \sqrt{\frac{Z_0 - R_a}{4\pi^2 f^2 Z_0^2 R_a}}$$

where $Z_0 > R_a$

$$X_1 = \frac{Z_0 R_a}{\pm \sqrt{R_a(Z_0 - R_a)}}$$

$$= \frac{1}{2\pi f C_B}$$

where, in Fig. 82, C_B is dependent only on values of Z_0 and R_a, where Z_0 is equivalent to a pure a-c resistance with the antenna circuit adjusted for resonance. *Unless Z_0 exceeds the value of R_a, an effective resistance equivalent to the characteristic impedance of the line cannot be secured.*

When low-impedance lines are used, such as the concentric-tube type, the termination shown in Fig. 83 is useful, since it affords a condition where correct termination may occur in the form of an effective resistance even though R_a equals or exceeds Z_0.

In Fig. 84 is shown a transmission-line termination in the form of a tank circuit. The tank capacitor C_B across the line is selected so as to provide a suitable kva ratio of the tank circuit with respect to the kilowatts transferred to the antenna circuit; this kva/kw ratio is normally about 10 and should never be less than 2.

$$X_1 = \frac{Z_0 R_e}{\pm \sqrt{R_e(Z_0 - R_e)}}$$

$$X_1^2 = \frac{Z_0^2 R_e}{Z_0 - R_e}$$

from which

$$R_e = \frac{X_1^2 Z_0}{Z_0 + X_1^2}$$

where R_e is the effective value of resistance reflected into the tank circuit from the antenna circuit.

The value of R_e can be calculated from

$$R_e = \frac{\omega^2 M^2 R_a}{R_a^2 + X_a^2}$$

where the inherent resistance of the tank circuit is negligible, M = mutual inductance between L_A and L_B, X_a = reactance of antenna circuit, and R_a = resistance of antenna circuit.

For a condition of proper termination X_a approaches zero and may be neglected and

$$\frac{\omega^2 M^2}{R_a} = \frac{X_1^2 Z_0}{Z_0^2 + X_1^2}$$

$$M = \sqrt{\frac{X_1^2 Z_0 R_a}{\omega^2 (Z_0^2 + X_1^2)}}$$

In Fig. 85 are shown values of M required for line impedances of 400, 500, and 600 ohms and a line-termination capacitor of between 0.001 and 0.004 μf. The

transmitter frequency was assumed as 670 kc and the antenna resistance as 30, 70, and 140 ohms. In the design of a tank-circuit termination for a given line the value of C_B across the line is selected so as to provide the proper kilovolt-amperes in the tank circuit with respect to the power transferred to the antenna circuit.
FIG. 85. Values of M required for proper termination.

71. Termination Adjustments. The usual procedure in adjusting a transmission-line termination for a condition of no wave reflection on the line is as follows:

1. The number of coupling turns is calculated so as to give the proper value of M. With the tank circuit open, the antenna is tuned to exact resonance by means of an external oscillator loosely coupled to it at the fundamental frequency.
2. The tank circuit is now connected into the circuit and tuned to resonance. This is indicated by a condition where the current in the antenna circuit becomes a minimum.
3. The transmission line is then connected across the tank circuit without making any changes in previous adjustments.
4. Correct termination may be checked by measuring the transmission-line currents at the ends and $\lambda/4$ points along the line. When proper termination has been effected, the transmission-line currents will be identical at all points along the line.

72. Concentric Line Terminations. The extensive use of concentric lines of the low-impedance type has led to cases where the characteristic impedance of the line is *lower* than that of the antenna resistance. In general there are three cases to consider,

as follows: (1) when the antenna impedance contains a resistance component only, (2) when the antenna impedance contains a resistance component and a reactance component, either (*a*) capacitive or (*b*) inductive, and (3) when the antenna impedance contains resistive and reactive components, the latter being partially compensated by the insertion of an extra reactance of opposite sign. These three cases are considered in order.

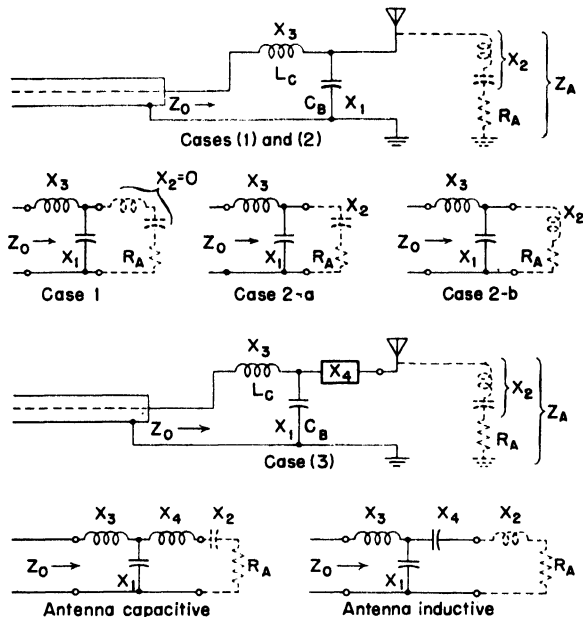
Case 1. *Antenna Impedance Purely Resistive.* From Fig. 86 the concentric-line characteristic impedance Z_0 is terminated by a network consisting of C_B, L_C, and the antenna


Fig. 86. Concentric-line terminations.

impedance Z_A. For case 1 the reactance of the antenna impedance is zero, and

$$Z_0 < Z_A = R_A$$

Then the complex impedance Z_L presented to the end of the transmission line is as follows:

$$Z_L = \frac{R_A[X_3X_1 - X_1(X_3 - X_1)] + j[X_3X_1^2 + R_A(X_3 - X_1)]}{R_A^2 + X_1^2}$$

where R_A, X_1, and X_3 are given in Fig. 86. For proper termination Z_0 must equal Z_L. X_1 becomes

$$X_1 = R_A \sqrt{\frac{Z_0}{R_A - Z_0}}$$

$$X_3 = \frac{R_A^2X_1}{X_1^2 + R_A^2}$$

Since $C_B = 1/(2\pi fX_1)$ and $L_C = X_3/(2\pi f)$, their values in microfarads and microhenrys are then readily calculable from f, the frequency of operation. Figure 87 gives various values of X_1 and X_3 in terms of values of Z_0 and R_A.

Case 2*a*. *Antenna Impedance with Capacitive Reactance.* Refer again to Fig. 86. It will be noted that the equivalent diagram for case 2*a* is the same as for case 1, except that
Fig. 87. Reactances required for proper line termination.
Fig. 88. Values of terminating reactances for case 2a.

the antenna impedance is now $Z_A = R_A - jX_2$. Then

$$Z_L = Z_0$$

$$Z_0 = \frac{R_A X_1^2}{R_A^2 + (X_2 + X_1)}$$

from which

$$X_1 = \frac{Z_0}{R_A - Z_0}\left[X_2 \pm \sqrt{\frac{R_A}{Z_0}(R_A^2 + X_2^2 - Z_0 R_A)}\right]$$

$$X_3 = \frac{X_1(R_A^2 + X_2 X_1 + X_2^2)}{R_A^2 + (X_1 + X_2)^2}$$

Hence, with Z_0, R_A, and X_2 given, X_1 and X_3 can be calculated. From the values of X_1 and X_3, L_C and C_B can be calculated, exactly as in case 1. Values of X_1 and X_3 for various values of R_A and values of X_2 for the cases where Z_0 is 80 and 100 ohms are given in Fig. 88.
FIG. 89. Terminating reactances for case 2b.

Case 2b. Antenna Impedance Inductively Reactive. Case 2b is the same as case 1 except that $Z_A = R_A + jX_2$.

$$X_1 = \frac{Z_0}{R_A - Z_0}\left[-X_2 \pm \sqrt{\frac{R_A}{Z_0}(R_A^2 + X_2^2 - Z_0 R_A)}\right]$$

$$X_3 = \frac{X_1(R_A^2 + X_2^2 - X_2 X_1)}{R_A^2 + (X_2 - X_1)^2}$$

from which L_C and C_B are calculated. Figure 89 shows various values of X_1 and X_3 in terms of R_A and X_2, for Z_0 values of 80 and 100 ohms.

Case 3. Added Reactance to Antenna Impedance. When the transmission-line impedance "looks into" a complex antenna impedance, it is possible to simplify the adjustment of the circuit greatly by adding a reactance X_4 as shown in Fig. 86 for case 3. This reactive X_4 may be either inductive or capacitive, as shown. If the sum of X_3 and X_2 is inductive, then X_4 is made capacitive, and vice versa. The value of X_4 is such that the algebraic sum of X_1, X_2, and X_4 is equal to zero. Since X_4 is in series with the antenna impedance, it adds directly with the reactive part of the antenna impedance. The effect of the presence of X_4 can then be taken into account by applying the formulas of case 2a or 2b.

$$X_1 = X_3 = \sqrt{Z_0 R_A}$$

This occurs only, however, if X_4 is so chosen that

$$\pm X_4 - X_1 \mp X_2 = 0$$

The reactance X_4 must always have the opposite sign from X_2, as indicated by the plus-or-minus signs in the equation. When X_4 is so chosen, the reactance X_1 and X_3 may be obtained for various values of Z_0 and R_A by reference to Fig. 90. Note that these values apply regardless of whether R_A is larger than, equal to, or greater than Z_0.

Practical Procedure in Designing Matching Circuits. In making suitable adjustments on the impedance matching circuits to provide a correct termination for a given
FIG. 90. Terminating reactances for case 3 when antenna reactance is compensated.

transmission-line characteristic impedance, under cases 2*a* and 2*b* above, where $R_A > Z_0$, the following procedure is recommended:

1. The transmission-line characteristic impedance should be calculated and the results checked by actual measurements if possible, either by means of an r-f impedance bridge or by the method described previously.
2. The antenna base resistance should be measured over a frequency band covering at least 100 kc each side of the operating frequency. A curve should then be constructed with values of antenna resistance as a function of frequency. A smooth curve drawn through the points of measurements will assist in checking their accuracy.
3. Together with antenna resistance measurements, the antenna reactance should be measured, either by means of an r-f impedance bridge or in a manner shown in Fig. 92 over a wide frequency range, and a curve constructed with antenna reactance as a function of frequency.
4. With the values of antenna resistance and reactance known, values of C_B and L_C may be calculated for case 2*a* or 2*b*, as may be required, and connected into the circuits as shown in Fig. 86.
5. With the transmission line connected, correct termination may be checked by measuring the transmission-line currents at the ends, if its length is equal to $\lambda/4$ or odd multiples thereof. For a very long line it is good practice to make these measurements at a number of points along the line. The existence of stationary waves of current or voltage of the fundamental frequency along the line is an indication of incorrect termination. In such a case slight adjustments may be necessary in L_C and L_B to correct for stray capacitance of leads and tuning equipment or slight errors in measurements. If an r-f impedance bridge is available, its measuring terminals may be connected across the input to the matching circuit in place of the transmission line and the termination circuit checked for an effective resistance equivalent to the characteristic impedance of the line without the line attached.

Case	Antenna current I_A	Current through capacitor C_B: $I_C\left(\frac{Z_A}{Z_A+Z_B}\right)=I_B$	Transmission line current $I_A\sqrt{\frac{R_A}{Z_0}}=I_C$	Voltage at base of antenna $E_A=I_AZ_A$
1	$\sqrt{\frac{W}{R_A}}$	$I_C\left[\frac{R_A^2+jR_AX_1}{R_A^2+X_1^2}\right]$	$\sqrt{\frac{W}{Z_0}}$	I_AR_A
2a	$\sqrt{\frac{W}{R_A}}$	$I_C\left[\frac{R_A^2+X_1X_2+X_2^2+jR_AX_1}{R_A^2+(X_2-X_1)^2}\right]$	$\sqrt{\frac{W}{Z_0}}$	$I_A(R_A-jX_2)$
2b	$\sqrt{\frac{W}{R_A}}$	$I_C\left[\frac{R_A^2-X_1X_2+X_2^2+jR_AX_1}{R_A^2+(X_2-X_1)^2}\right]$	$\sqrt{\frac{W}{Z_0}}$	$I_A(R_A+jX_2)$

W is power in watts				

FIG. 91. Current and voltage relations in transmission-line terminating circuits.

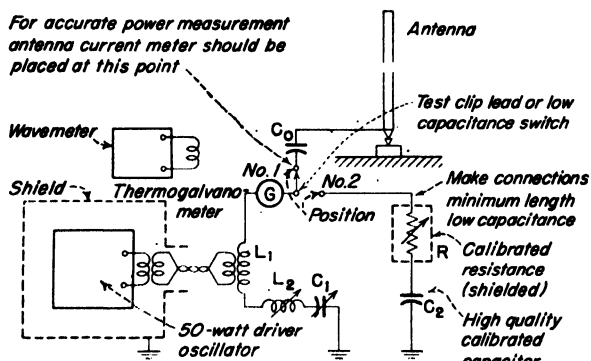
Although case 3 requires the addition of another piece of apparatus in the form of an inductance or capacitance in the antenna lead, which may be rather expensive, the adjustment procedure is less difficult and is as follows:


FIG. 92. Setup for measuring antenna characteristics.

1. With values of the line characteristic impedance, antenna resistance, and reactance obtained by measurement, the value of C_B is calculated, which gives the reactance X_1 necessary.

2. With L_C disconnected from C_B, X_4 (inductive or capacitive) is added in the antenna circuit in series with X_1. By means of X_4 the antenna circuit is tuned to resonance, as indicated by maximum current through a thermogalvanometer, when the antenna circuit is excited by means of an external oscillator loosely coupled to it.

3. A sufficient value of inductance L_C having a value X_3 equal to X_1 is then connected into the circuit as shown in Fig. 86.

4. The line is then checked for stationary waves, the absence of which indicates a condition of correct termination.

The mechanical properties of long concentric-tube transmission lines makes the measurement of current in the center conductor rather difficult. In some cases removable plugs are placed in the outside tube at various intervals along the line. These plugs, which, when inserted, make the outer tube airtight, permit connections from an antiresonant circuit across the line. Such an antiresonant circuit, when tuned to the fundamental frequency, presents a very high impedance to the line, when bridged across it, and therefore does not affect its characteristic impedance at the fundamental frequency. With about 10 watts flowing through the line, the galvanometer reading is an indication of the voltage at the points measured along the line.

Fig. 93. Matching circuits for balanced transmission line.

73. Method Used in Measuring Antenna Characteristics. Refer to Fig. 92.

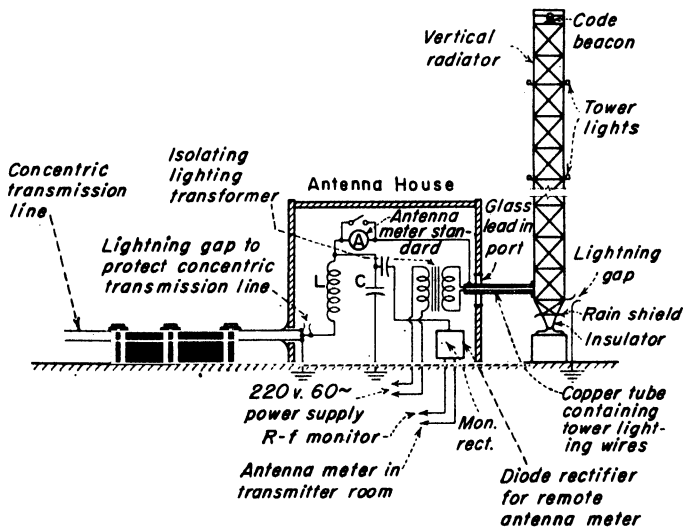
C_0 (usually about 0.0005 μf) is selected to provide sufficient series capacitance-reactance to make the antenna capacitive over the frequency range measured. Then, with the antenna excited by the driver oscillator at the frequency indicated by the wavemeter and the switch at position 1, adjust C_1 and L_2 for resonance, as indicated by the maximum reading of G. R is then adjusted until the G reading is the same as before. Then R is the antenna resistance.


Fig. 94. Equipment in antenna house of modern broadcast transmitter.

For antenna reactance measurement, the circuit is first calibrated for stray capacitance in the shielded resistance box by resonating circuit (switch in position 2) first with box in the circuit and then entirely removed. Difference in reading of C_2 between the two conditions

equals capacitance of box. This value should be added to each reading of C_2, when circuits are resonated, which is done as above for resistance measurement. The antenna reactance X_2 is equal to the reactance of C_2 minus that of C_0. When reactance of C_0 is greater than that of C_2 the antenna reactance is positive.

When it is found desirable to apply the matching circuits described above (Fig. 86) to balanced lines (open wire or double concentric types), the value of X_3 derived by the particular formula for cases 1 and 2 is halved and placed on each side of the circuit (see Fig. 93), while the value of X_4 is halved and placed on each side of the circuit for case 3. Under these conditions the formulas given above apply to the respective cases mentioned. The systems become quite useful in matching a given balanced transmission line or r-f circuit into another having entirely different input impedance characteristics.

In the foregoing analysis of antenna matching circuits, they were considered as providing, for a given transmission line, a termination impedance equivalent to an ohmic resistance at the fundamental frequency. An analysis of the input impedance that such a line "looks into" at various harmonic frequencies discloses that it may assume an infinite number of different impedances containing resistance and positive or negative reactance components, the values of which depend upon the termination circuit constants as well as those of the antenna. The values of antenna resistance and reactance may vary widely with frequency. For harmonic frequencies, stationary waves of current and voltage will form on the transmission line as well as in the antenna circuit, unless suitable harmonic filtering is provided either within the vacuum-tube transmitter or at the input to the transmission line.
Relationship along line any variation voltage or current

$$\frac{\partial I}{\partial S} = EG + C\frac{\partial E}{\partial t} \qquad \frac{\partial E}{\partial S} = IR + L\frac{\partial I}{\partial t}$$

Assume sinusoidal variation of the current and voltage at any point along the line a distance S from transmitter

$$I = I_T \cosh S\sqrt{ZY} - E_T\sqrt{Y/Z}\sinh S\sqrt{ZY} \qquad E = E_T \cosh S\sqrt{ZY} - I_T\sqrt{Z/Y}\sinh S\sqrt{ZY}$$

When the line is aperiodic surge impedance $Z_0 = \sqrt{\frac{R+j\omega L}{G+j\omega C}}$

Components contributing to line loss:

Δe_1 = Voltage consumed in phase with current

Δi_1 = Current consumed in phase with voltage

Voltage E_S at any point S distance from transmitter end

$$E_S = E_T e^{-s(\alpha+j\beta)} = E_0 e^{-S\sqrt{(R+j\omega L)(G+j\omega C)}}$$

where α = attenuation constant for lines of small leakage conductance $\alpha = \doteq \left(\frac{R}{2} + \frac{GL}{2C}\right)\sqrt{C/L}$

For lines having negligable leakage $\alpha \doteq \frac{R}{2}\sqrt{\frac{L}{C}} = \frac{R}{2Z_0}$

$A \doteq 4.343\frac{R}{Z_0}$ decibels per unit length

FIG. 95. Losses in transmission lines.

The effectiveness of a given filter for various harmonics depends upon its position in the line with respect to the positions of current and voltage antinodes of the harmonic frequencies along the line.

74. Loss in R-f Transmission Lines. From Fig. 95, it is evident that the most prominent factors contributing to power loss in open-wire transmission lines are as follows:

1. Power loss due to conductor thermal resistance for two-wire line

$$R_T = \frac{0.1262}{d}\sqrt{\rho\mu f} \qquad \text{ohms per cm length}$$

where $S >> d$ (see Fig. 80)

ρ = resistivity of conductors, in ohms per cm cube
μ = permeability of conductors
f = frequency, Mc
d = diameter of conductor, cm

2. Power radiated from balanced and unbalanced line currents
3. Power component of mutual inductance due to secondary currents induced in nearby conductors
4. Power loss due to leakage or conductance of the insulating medium or

$$G = \frac{\gamma A}{l} \qquad \text{mhos per cm length}$$

5. Power loss due to dielectric hysteresis

NOTE: The resistivity of copper is approximately 1.724×10^{-6} ohm per cm cube at 20°C. The exact value of a particular grade of copper depends upon the amounts of other elements it may contain.

For coaxial lines the major factors contributing to power loss in transmission lines are as follows:

1. Power loss due to conductor thermal resistance

$$R_T = 0.0631\sqrt{\rho\mu f}\left(\frac{1}{d_1} + \frac{1}{d_2}\right) \qquad \text{ohms per cm of line}$$

where d_1 = outside diameter of inner conductor, cm
d_2 = inside diameter of outer conductor, cm
ρ = resistivity of conductors, in ohms per cm cube
μ = permeability of conductors
f = frequency, Mc

2. Power loss due to leakage conductance of insulating medium
3. Power loss due to dielectric hysteresis
FIG. 96. Power loss in lines operating at 20°C with negligible reflection.

By reference to the loss curves shown in Fig. 96, it is evident that the greater part of the power loss in both the open-wire and coaxial types when operating with negligible reflection is due to the conductor thermal resistance. Owing to the low-loss insulation materials now available, the losses due to dielectric leakage and hysteresis can be reduced to a negligible quantity especially at standard broadcast frequencies.

The curves of Fig. 96 are the results of extensive r-f measurements which confirmed mathematical formulas given for calculation of losses in open-wire and coaxial lines of various standard sizes. Worthy of mention is the rather high efficiency of the open-wire line consisting of two No. 4 B&S gage solid copper conductors spaced 12 in. center to center. The losses in this line are less than those in a 3-in.-diameter copper coaxial line. The resistivity ρ of aluminum being greater than copper, the losses in an aluminum coaxial line are somewhat greater than those in a copper line of the same dimensions.

FIELD STRENGTHS REQUIRED AND MEASURED

75. Broadcast-station Signal Coverage. The reception of satisfactory signals from a given broadcasting station by a particular listener at a given point depends upon the following: (1) the intensity of the signal radiated from the antenna system of the station as influenced by the radiated r-f carrier power, antenna directivity, and percentage of modulation on the carrier; (2) distance between the transmitting antenna and the point of reception and the attenuation characteristics of the intervening space or terrain; (3) intensity of objectionable interference at the receiving point; (4) fading as produced by the rays of direct and indirect signals; (5) the quality of the receiver and its ability to discriminate against local noise or interference and against adjacent channel interference and to convert the receiver r-f signals into sound without appreciable distortion or inherent receiver noise. The surrounding area about a given station wherein satisfactory program signals can be received determines the service area of the station.

The service area of a station of the 550- to 1,600-kc band consists essentially of two distinct regions. The region in close proximity to the station is served by the direct ray or ground wave called the *primary coverage area*, while the region at some distance from the station and served by virtue of indirect ray or sky-wave reflections is called the *secondary coverage area*. During daylight hours on frequencies between 550 and 1,600 kc, a broadcast listener is concerned with the primary coverage area signals of nearby stations since there is very little sky-wave energy reflected during this period under normal conditions. The daylight service area of such a station therefore consists almost entirely of that region served by the direct ray.

During the hours of twilight and darkness, the secondary coverage area of stations in the standard broadcast band becomes apparent. The secondary coverage area of a particular station begins at a considerable distance from a given station and is served by the predominant sky wave. The primary and secondary coverage areas are separated by a region known as the *fading area*. In this area the signal intensities of the direct and indirect rays approach an equality with a result that violent fluctuations in signal intensities are apparent. The fading areas are dependent upon a number of factors, such as frequency, antenna, radiation characteristics, conductivity of intervening terrain, and time of day and season, and are independent of the transmitter powers of the stations. The fading area is normally in the form of a band about the station normally contained within radii of between 20 and several hundred miles, depending upon the factors mentioned. The fading band may be as much as 50 miles in width.

Considering a standard broadcasting station radiating equally in all directions over surrounding terrain, and assuming equal ground attenuation, the service area would consist of a primary coverage area near the station and served by a steady ground-wave signal. Outside of this would exist the fading area consisting of a ring about the primary area. Beyond the fading ring the secondary coverage area will exist. Inasmuch as broadcast reception is rather uncertain in the fading region and in the

secondary coverage area, the real value of a given station is dependent normally upon its primary coverage area.

The primary service area of a particular station can be most accurately determined by means of a field-intensity survey. A survey[1] of this kind is accomplished through the use of mobile field-intensity measuring equipment. This consists essentially of a field-intensity meter or carefully shielded receiver equipped with an indicating meter at its output terminals to read carrier-signal intensity as induced in the loop antenna. The field-intensity meter and the loop antenna are carefully calibrated in their position in the measuring car to give accurate readings in microvolts per meter over a wide range of carrier-signal intensity.

76. Field-intensity Measurements. The procedure of making a field-intensity survey of a broadcasting station consists usually of making frequent measurements at satisfactory positions (in free space) along radials progressing to and from the station. Eight or more radials at equal angular spacing are generally made about a point established on the field survey map by the station antenna system and extending to a signal intensity of 500 mv or beyond. Each radial is then plotted on loglog paper and a smooth curve drawn through these points to show directly the signal intensity along one ordinate, with distance along the other. Later the values required are transferred to a map in the form of signal contour lines representing positions about the station where field intensities of 100, 50, 10, 2, and 0.5 mv per m exist. The contour map for reference purposes also contains information such as (1) station call letters, (2) frequency, (3) antenna power and its directivity and other characteristics, (4) scale of map, and (5) date.

Since fading occurs after sunset these measurements are an indication of satisfactory daytime coverage only from the particular station. As recommended by reports of the IRE,[2] FCC,[3] and the National Association of Broadcasters, values of standard broadcast field intensity considered necessary for reliable broadcast service are given for three areas as follows: (1) a business city area where a field intensity of from 10 to 50 mv per m is required to override high interfering electrical noise and overshadowing effects of large buildings, (2) a residential district of a city where a field intensity of 2 to 10 mv per m is required, (3) a rural area where 0.1 to 0.5 mv per m signal intensity is sufficient. In addition it is stated that for fair service a signal intensity of one-half the above values is needed and for poor service one-fourth of these values. These figures are based upon the average signal intensity necessary to override the noise levels of these districts. In large cities, where large, tall buildings are numerous, a free-space field intensity of as much as 50 mv per m over the city may be necessary to provide a signal intensity at a particular receiving antenna between buildings.

Since the primary service area of a standard broadcasting station includes nighttime reception as well as daytime, fading measurements are necessarily a part of the field-intensity survey in determination of this area. Fading measurements are made with the same field-intensity measuring equipment used for the survey except that the field-intensity meter is equipped with a recording milliammeter (usually of 0 to 5 ma range) attached to the output of the field-intensity meter. A d-c amplifier sometimes is necessary to secure sufficient signal level to actuate the recording meter from the field-intensity measuring set. The equipment is set up for periods of time at a given distance and location from the station, and fluctuations in carrier-signal intensity are noted on the continuously moving recording chart. Amplitude fluctuations as recorded on the chart indicate the amount of fading. Fading measurements for considerable periods of time and over a wide area are necessary to determine the fading region about a given station and to evaluate the secondary coverage area about the station, particularly those designated as class I stations.

[2] Report of Committee on Radio Propagation Data, *Proc. IRE*, **21** (10), October, 1933.

[3] Fifth annual report to the Congress of the United States, by Federal Communications Commission, gives tabulated values of field strength.

Field-intensity measurements for v-h-f broadcasting stations are made in a manner similar to that for standard broadcasting with the exception that a different type of field-intensity measuring equipment is required and that the procedure for making fading measurements is not generally required.

77. Calculations of Station Coverage. A mathematical investigation of the attenuation of radio waves propagating over plane earth has led to expressions which follow very nearly the characteristics of waves as indicated by actual measurements. A simplified form of this expression requires the following information for a solution: (1) frequency, (2) distance from the station, (3) conductivity of the soil in electromagnetic units, and (4) inductivity of the soil in electrostatic units. Since the inductivity can be generally assumed to be 14 to 15 esu, then, with a measured value of conductivity σ, the field intensity at a given distance from a station may be calculated. With further assumptions concerning the irregularities in general characteristics of the terrain about the station, it is possible to calculate the contours. The value of σ (the soil conductivity) is usually secured from a measured radial or taken from available field-intensity measurements of some other station in the vicinity. The FCC has published charts showing soil conductivity over the United States. Provided measured values are not available, these may be used.

For convenience the chart shown in Fig. 97 is given. It may be used to calculate signal attenuation of standard broadcast frequencies. The attenuation curves shown are derived from a simplified form of Sommerfeld's attenuation formula.[1] With a single set of Sommerfeld curves to cover all the standard broadcast frequencies and soil conductivities, the conductivity of a given soil can be rather easily computed from the attenuation of a particular signal. This is accomplished by first converting a given radial to an inverse field strength of 1,000 mv at 1 mile and then determining the frequency of the ground-wave curve with which it coincides, *i.e.*, the conversion frequency. The conductivity is secured from the soil-constant curve passing through the intersection of the operating and conversion frequencies on the conversion chart in the upper right corner of the figure. The conversion chart has been prepared from the following relationships:

$$f_1 = f\sqrt{\frac{\delta}{\delta_1}}$$

where f = operating frequency
δ = standard conductivity of chart (100×10^{-15} emu)
δ_1 = actual soil conductivity
f_1 = conversion frequency

For example, assume a station operating on 660 kc where the field strength radial, as plotted from measurements, follows the 1,500-kc curve. Then, from the soil conversion chart, the conductivity is very nearly 20×10^{-15} emu. On the other hand, if the soil conductivity is known, the signal attenuation can be determined from the conversion chart and the attenuation curves of various frequencies. Since these curves are based on a field strength of 1,000 mv at 1 mile, the actual signal at a given distance from a station is, of course, derived from the ratio of the actual signal intensity in millivolts at 1 mile from the particular station divided by 1,000. At considerable distances from the transmitter these curves are subject to corrections for the effects of curvature of the earth.

The curves in Fig. 98 refer to sky-wave intensities under various conditions of

For FCC curves of standard broadcasting-station propagation, refer to curves of FCC rules, Part 3, Secs. 3.184 and 3.186, U.S. Government Printing Office, Washington.

propagation. These are most useful in the determination of the fading regions about a particular station and are plotted to give intensities of reflected sky-wave intensity for different antenna electrical heights based on a signal intensity of 1,000 mv along the ground at 1 mile from a given antenna. In this case the electrical height of the
FIG. 97. Ground-wave field-intensity curves.

antenna in degrees equals $3.85 \times 10^{-4}Hf$, where H is the physical height of the antenna in feet and f is the operating frequency in kilocycles. This is based on a velocity of propagation equivalent to 0.95 that of light.

Inasmuch as the attenuation curves of ground-wave intensity (Fig. 97) are also based on 1,000 mv at 1 mile, then the particular distance from a given antenna where the sky-wave intensity, shown on curves of Fig. 98, equals the ground-wave signal

intensity of Fig. 97 is the distance from the antenna where one would expect to observe greatest fading or is an estimate of the center of the fading band. Owing to the height of the Heaviside layer being other than 100 km and reflection being less than unity, on which these curves are based, calculated distances given by these curves
FIG. 98. Sky-wave propagation curves for antennas of various heights. Layer height = 100 km; reflection coefficient = 1.
FIG. 99. Average sky-wave field intensity, 640 to 1,190 kc.

are approximate. Measurements are required for more exact determination of the fading region.

The service rendered by a standard broadcast station depends also on interference caused by other stations on the same and nearby channels. This interference is greatly increased at night because signals from undesired distant stations are reflected by the Heaviside layer and may be received with varying intensities within the service

area of a desired station. Following extensive survey work covering nighttime signal propagation over the period February to May, 1936, the FCC issued a report[1] wherein a great amount of information concerning sky-wave propagation is given. In Fig. 99 are illustrated curves representing the average sky-wave field intensity (second hour after sunset) at the recording station. An interfering or undesired signal existing for 10 per cent of the time has been standardized as an interfering signal. Thus, with the antenna sky-radiation characteristics of a given station known,[2] it becomes possible to estimate the amount of undesirable interference it is liable to cause to another distant station. In the determination of interference problems, the FCC has issued under Sec. 3.182W of its rules Table 4 to be used for determining the minimum ratio of the field intensity of a desired to an undesired signal for interference-free service.

Table 4. Interference Ratios

Frequency separation of desired to undesired signals, kc	Desired ground wave to		Desired 50% sky wave to undesired 10% sky wave
	Undesired ground wave	Undesired 10% sky wave	
0	20:1	20:1	20:1
10	1:1	1:5	*
20	1:30		

* The secondary service area of a class I station is not protected from adjacent channel interference. However, if it is desired to make a determination of the area in which adjacent channel ground-wave interference (10 kc removed) to sky-wave service exists, it may be considered as the area where the ratio of the desired 50% sky wave of the class I station to the undesired ground wave of a station 10 kc removed is 1:4.

When the desired ground-wave signal is interfered with by two or more sky-wave signals on the same frequency, the rss value of the latter is used.

From the above, it is apparent that in many cases stations operating 10 and 20 kc apart may be operated with antenna systems side by side or otherwise in proximity without any indications of interference if the interference is defined only in terms of permissible ratios listed above. As a practical matter, serious interference problems may arise when two or more stations with the same general service area are operated on channels 10, 20, and 30 kc apart.

The FCC has classified standard broadcast stations with respect to protected service contours and permissible interference signals in accordance with Table 5 under Sec. 3.182V of the FCC rules.

78. V-h-f broadcast-station coverage concerns the stations licensed by the FCC primarily for transmission in the v-h-f broadcast band for reception by the general public. The v-h-f broadcast band extends from 88 to 108 Mc. Stations in this band must use f.m. The assigned operating frequency or "center frequency" is that of the r-f carrier without modulation. It must be maintained within 2,000 cps of the assigned center frequency assigned. Channels for v-h-f broadcast stations begin at 88.1 Mc and continue in successive steps of 200 kc to and including the assigned frequency of 107.9 Mc.

According to the FCC rules, v-h-f broadcast stations shall be licensed on the basis of an area in square miles within the service area. The contour bounding the service area and the radii of same are determined in accordance with the FCC standards. On this basis, a v-h-f broadcast station has a single service, that corresponding to the primary service of a standard broadcast station. Secondary (sky-wave or intermittent) service is not recognized in v-h-f broadcast coverage.

[1] FCC Report 18108, September, 1936.
[2] FCC rules, Sec. 3.190, Fig. 1.

Table 5. Protected Service Contours and Permissible Interference Signals for Broadcast Stations

Class of station	Class of channel used	Permissible power, kw	Signal-intensity contour of area protected from objectionable interference,[a] μv/m		Permissible interfering signal on same channel,[b] μv/m	
			Day[c]	Night	Day[c]	Night[d]
I-A	Clear	50	SC 100 AC 500	Not duplicated	5	Not duplicated
I-B	Clear	10–50	SC 100 AC 500	500 (50% sky wave)	5	25
II	Clear	0.25–50	500	2,500 (ground wave)	25	125
III-A	Regional	1–5	500	2,500 (ground wave)	25	125
III-B	Regional	0.5–1 night and 5 day	500	4,000 (ground wave)	25	200
IV	Local	0.1–0.25	500	Not prescribed[e]	25	Not prescribed[e]

[a] When it is shown that primary service is rendered by any of the above classes of stations, beyond the normally protected contour, and when primary service to approximately 90% of the population (population served with adequate signal) of the area between the normally protected contour and the contour which such station actually serves is not supplied by any other station or stations, the contour to which protection may be afforded in such cases will be determined from the individual merits of the case under consideration. When a station is already limited by interference from other stations to a contour of higher value than that normally protected for its class, this contour shall be the established standard for such station with respect to interference from all other stations.

[b] For adjacent channels see appropriate paragraph of the FCC rules.

[c] Ground wave.

[d] Sky-wave field intensity for 10% or more of the time.

[e] These values are with respect to interference from all stations except class I-B, which stations may cause interference to a field-intensity contour of higher value. However, it is recommended that class II stations be so located that the interference received from class I-B stations will not exceed these values. If the class II stations are limited by class I-B stations to higher values, then such values shall be the established standard with respect to protection from all other stations.

V-h-f broadcast transmitters are normally located as near to the center of the proposed service area as possible. A high elevation of the transmitting antenna is necessary to reduce the shadowing effects upon propagation due to hills, buildings, and other obstructions in the city area. The position of the transmitter site is also dependent upon the purpose of the station, *i.e.*, whether it is intended to serve a small city, a metropolitan area, or a large region. A suitable transmitter site may be made available by the use of a directive antenna. Where a directive antenna is used, a centrally located station site may not be a desirable one. As one may understand by studying the chart in Fig. 100, the transmitter antenna height above the average elevation of the service area is a consideration of greatest importance to secure optimum coverage.

Table 6. Allowable Signal Ratios

Channel Separation	Ratio of Desired to Undesired Signals
Same channel	10:1
Adjacent channel (200 kc removed)	2:1
400 kc removed	1:10
600 kc removed	1:100
800 kc removed and above	No restriction

In the consideration of objectionable interference from other stations on the same and adjacent channels, the FCC[1] rules require that the proposed station shall not have interference to such an extent that its service may be reduced to an unsatisfactory amount. For this reason, objectionable interference is considered to exist when the interfering signal exceeds that given by Table 6. In this table the desired signal is

[1] FCC Rules 3.313b.

the median field intensity, and the undesired signal is the tropospheric signal intensity exceeded for 1 per cent of the time.

The FCC[1] rules concerning frequency-carrier separation of v-h-f stations further state:

Stations normally will not be authorized to operate in the same city or in nearby cities with a frequency separation of less than 800 kc: *Provided*, That stations may be authorized
Fig. 100. Signal range for v-h-f broadcast stations.

to operate in nearby cities with a frequency separation of not less than 400 kc where necessary in order to provide an equitable and efficient distribution of facilities: *And provided further*, That class B stations will not be authorized in the same metropolitan district with a frequency separation of less than 800 kc. In the assignment of FM broadcast facilities the Commission will endeavor to provide the optimum use of the channels in the band, and accordingly may assign a channel different from that requested in an application.

Objectionable interference is not considered to exist when the channel separation is 400 kc or greater. Therefore f-m broadcast stations in the same city or area may be assigned channels 400 kc apart.

[1] FCC Rules 3.313c.

The service area of f-m broadcasting stations is considered to be only that served by the ground wave. The extent of the service is determined by the point at which the ground wave is no longer of sufficient intensity to provide satisfactory service. The standard of field intensity necessary for satisfactory service is given as follows:

Table 7. Service

Area	Median Field Intensity, Mv/m
City areas near factories, car lines, or busy streets	1
Rural areas away from highways	0.050

The FCC rules[1] state that

. . . a median field intensity of 3,000 to 5,000 μv per m should be placed over the principal city to be served and a median field intensity of 1,000 μv per m should be placed over the business district of cities of 10,000 or greater within the metropolitan district served.

To determine the approximate distance to a particular contour of a v-h-f f-m station the chart in Fig. 100 may be used. The results obtainable are based on a signal intensity at a receiving antenna with an elevation of 30 ft. The distance to the 50 μv per m contour about a given station is dependent upon values of the transmitting antenna height, the antenna power, and the antenna gain. This chart is prepared for a carrier frequency of 98 Mc in the center of the f-m band and may be used for all f-m broadcast channels in the 88- to 108-Mc band with sufficient accuracy since little change results over this frequency range.

Examples: Consider (1) a northeastern metropolitan station and (2) a transmitter site 1,000 ft high with a 50-μv signal required at a distance of 70 miles from the transmitting antenna.

1. The radiated power of the northeastern station is assumed to be 20 kw at an antenna height of 500 ft. The problem is to predict the range in miles to the 1-mv contour. In Fig. 100, the dashed line between 20 kw and the 1 mv per m field intensity is drawn. This line intersects the microvolts for 1 kw line at 224 μv. A solid line then drawn between this point of intersection and the 500-ft transmitting-antenna-height point shows a distance of 32 miles.

2. Assume that there is required a 50-μv signal 70 miles away. Draw, between the 70-mile point and the point indicating 1,000 ft, a line which indicates that a radiated power of 1 kw from a station using an antenna 1,000 ft high would provide 21.5 μv at a distance of 70 miles. A solid line drawn between this point, the 0.050-mv point, and the power scale indicates that a transmitter power output of 5.5 kw is required to give a field intensity of 50 μv (0.050 mv) at a distance of 70 miles from the antenna radiating at an elevation of 1,000 ft above average ground at the transmitting station.

CHAPTER 22

TELEVISION

By Raymond F. Guy[1]

1. Definition. Television is the electrical transmission of transient visual images. Although the process is fundamentally simple an actual television system is one of great complexity.

2. Elements. A television camera tube employing an electron scanning beam reads off variations of voltage amplitude, corresponding to brightness, from a photosensitive surface upon which a picture image is focused. The image is recreated in a receiver picture tube when a corresponding synchronously modulated and deflected electron beam impinges upon a phosphorescent surface. Television systems normally contain facilities for synchronous transmission and reproduction of visual images and sound, but in some industrial applications the sound system may be omitted.

Figure 1 shows the elements of a typical system. The sound system consists of an f-m transmitter and receiver in which, under the FCC standards, a maximum frequency deviation of 25 kc corresponds to 100 per cent modulation. The sound system is operated in parallel with and separate from the picture system, except that common sound and picture antennas may be employed at both the transmitter and receiver and a common r-f amplifier, first detector, i-f amplifier, and second detector may be used in the receiver.

The picture transmitter includes the camera and synchronization circuits which create the video signals, video amplifiers, an r-f carrier source and r-f amplifiers, the modulator, a vestigial-side-band filter for suppressing part of the lower-frequency side bands from the transmitted signals, a sound and picture-signal diplexer for channeling both sound and picture signals to a common antenna, and the antenna.

The type of receiver most commonly used processes the sound and picture signals together up to the output of the second detector through antenna-to-receiver coupling circuits, a first detector, an i-f amplifier, and a second detector. Thereafter, there is a video amplifier, synchronizing-signal separator circuits, and a picture tube for the picture signals and a separate 4.5-Mc i-f amplifier, f-m sound demodulator, audio amplifier, and loud-speaker for the sound signals. The sound carrier appears at the output of the second detector as an f-m subcarrier of 4.5 Mc, which is the separation between the transmitted and received picture and sound carriers.

The receiver described and shown in Fig. 1 is referred to as the "intercarrier" type and is now more commonly used than older types which employed separate sound and picture i-f amplifiers and second detectors following the first detector.

SCANNING AND IMAGE ANALYSIS

3. Linear Scanning. The method of analyzing and synthesizing visual images employed in modern television systems is known as *linear scanning*. As applied to the transmission of images, linear scanning involves the exploration of the image by an elemental spot of small area, known as the *scanning agent*, which traverses the area of the image in a series of horizontal lines, moving over every point in the image at constant speed and discovering the degree of brightness at each point in

[1] Director of Radio Frequency and Allocations Engineering, National Broadcasting Company, Inc.

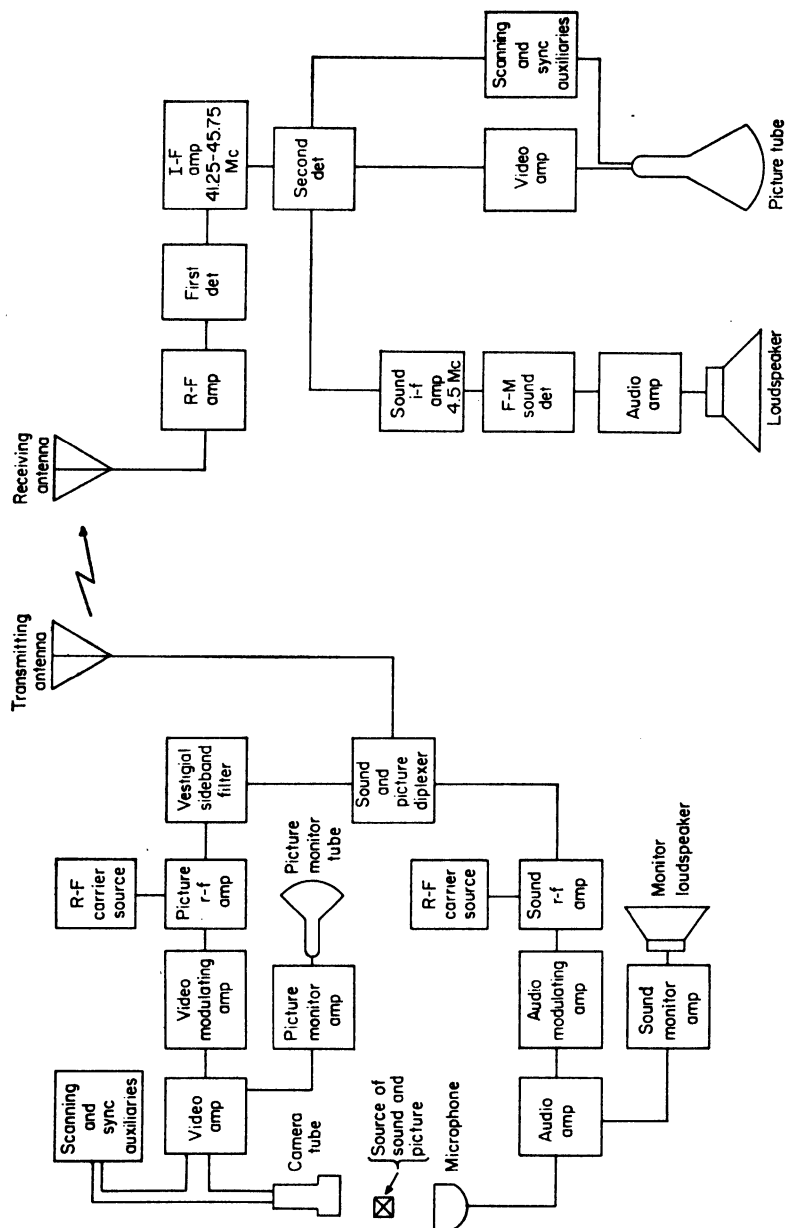
NOTE: This chapter draws freely on material written for the fourth edition of this book by Donald G. Fink.


FIG. 1. Elements of television system.

succession. The camera tube, which includes the scanning agent, generates a succession of electrical impulses which correspond with the successive values of brightness discovered by the scanning agent.

At the receiver the scanning process involves setting up an elemental luminous spot of small area which moves synchronously with the scanning agent in the camera tube.

The brightness of this luminous spot is controlled by the electrical impulses transmitted from the camera tube to the receiver. The values of brightness present in the original image are thereby reproduced in their proper positions. The scanning process must be rapid enough so that all the elements of the received image are perceived simultaneously by the eye. This requirement is met if the scanning of the image is completed within the duration of persistence of vision, so that the first element of brightness persists in the eye during the production of all the succeeding elements in the image.

4. Aspect Ratio. The ratio of width (w) to the height (h) of the rectangle actively employed in reproducing the image is known as the *aspect ratio.* In accordance with the standard adopted for motion pictures, in the United States this ratio is given the value

$$\frac{w}{h} = \frac{4}{3} \qquad (1)^*$$

5. Total Number of Lines per Frame. The total number of lines over which the scanning agent passes from the beginning of one complete image to the beginning of the next is known as the total number of lines per frame, n.

The number of lines determines the degree of detail which may be accommodated in the reproduced picture, in the vertical dimension. Hence this number sets an upper limit to the amount of pictorial detail which may be accommodated in that dimension. The number in modern systems is set usually between 400 and 700 lines. According to the FCC standards, n has the value

$$n = 525 \qquad (2)^*$$

The reason for the exact number 525 (see Secs. 6 and 34) is that it is an odd number composed of simple odd factors

$$525 = 3 \times 5 \times 5 \times 7$$

6. Interlaced Scanning. To reduce flicker in the reproduced image, a scanning technique known as *interlacing* is customarily employed, whereby the image is scanned in two groups of lines. The scanning motion in "two-field odd-line" interlaced scanning (the method now universally adopted) is shown in Fig. 2. The scanning agent traverses the area in two series of lines, alternately, passing downward (at left in Fig. 2) from point A to B in the light solid line, following the back-and-forth motions shown by the arrows. The scanning spot then moves upward from point B to C (at right), thence downward again from point C to D on the heavy line, finally upward again from point D to the starting point A, where the motion repeats itself. The scanning agent is active in discovering or reproducing the picture information while traveling over the lines shown solid and is inactive while traveling over the lines shown dashed. The total number of back-and-forth motions made in traversing both series of lines is n. The total number of active lines (shown solid) is n_a. The inactive lines ($n - n_a$)

FIG. 2. Scanning pattern for two-to-one odd-line interlaced scanning.

* Those relationships marked with an asterisk (*) are the official standards prescribed by the FCC for commercial television broadcasting.

are those made by the scanning agent in traveling from the bottom to the top of the picture area (the motions shown at the right). The number of active lines, n_a, for a 525-line image is approximately 490. The exact value of n_a is given by

$$n_a = \frac{n}{1 + b_v} \tag{3}$$

where b_v, the *vertical retrace ratio*, is the ratio between the upward and the downward scanning time, as defined in Sec. 7.

7. Scanning Velocities and Retrace Ratios. The scanning agent is made to traverse the picture area in the interlaced pattern (Fig. 2) by imparting to it horizontal and vertical motions. The spot is displaced horizontally from left to right during a time interval t_h sec, and simultaneously it is displaced vertically downward over a longer time t_v sec. The two motions cause the spot to move slightly downward and to the right until it reaches the right-hand edge of the area. Then the spot is reversed rapidly and is moved to the left in a fraction of the time occupied in moving from left to right. This fraction is the horizontal retrace ratio, b_h. Thus the complete back-and-forth horizontal motion occupies a time of $t_h(1 + b_h)$ sec. The downward motion persists during the succession of back-and-forth motions until the spot reaches the bottom of the area at the end of t_v sec. Thereupon the downward motion is reversed, and the spot is moved upward in a fraction, b_v, of the time consumed in the downward motion, until it reaches the top of the pattern. During the upward motion, several back-and-forth motions are executed, since the horizontal motions are maintained.

The *horizontal retrace ratio* b_h is the ratio of the backward (to the left) scanning time to the forward (to the right) scanning time. Practical values of b_h range from about 0.10 upward to 0.25. The FCC standards set an upper limit to this ratio of 0.15. The *vertical retrace ratio*, b_v, between the upward and the downward times, ranges from about 0.05 to 0.10. The FCC standards set an upper limit to this ratio of 0.08.

8. Interlaced Fields. One set of the two sets of lines in the interlaced pattern is known as an *interlaced field*. Since the total number of lines in the complete frame is an odd number (525), the number of lines per field is a whole number plus one-half (262½). This accounts for the fact that at the end of the first field (Fig. 2) the spot, at point C, has formed but one-half the horizontal motion. The half-line displacement causes the lines in the second field to be displaced vertically from those in the first field by the width of one line. Consequently the lines of one field fall directly between the lines of the preceding field. If the scanning motion is not accurately timed and if the amplitudes of the vertical and horizontal motions are not constant, this interlaced relationship is not maintained, and the lines of one field tend to overlap the lines of the preceding field. This defect is known as *pairing* of the fields. Its effect is to reduce the detail of the reproduced picture in the vertical dimension.

9. Vertical Resolution. The vertical resolution r_v of the scanning pattern is measured by the number of pictorial details or *picture elements* which may be accommodated in the vertical height of the picture area. Each active scanning line is capable of reproducing one such picture element in the vertical direction but, since the picture elements in the image to be transmitted may not fall directly on the scanning lines, the actual number of picture elements which may be accommodated vertically is less than the number of active scanning lines. The vertical resolution r_v is accordingly the number of active scanning lines multiplied by a factor less than 1, the utilization ratio k. The vertical resolution is accordingly

$$r_v = kn_a \qquad \text{elements per picture height} \tag{4}$$

Practical values of the utilization ratio, depending on the perfection of interlacing, range from about 0.6 to 0.9. With $n_a = 490$, r_v accordingly varies from 300 to 440 elements per picture height. The value $r_v = 350$ is commonly attained in properly operated equipment.

10. Horizontal Resolution. The horizontal resolution r_h of the scanning pattern is measured by the number of picture elements which may be accommodated in the

horizontal direction, measured in a width equal to the picture height. The picture height is used as the basis to make the horizontal resolution directly comparable with the vertical resolution. The total number of picture elements accommodated in the picture width is the horizontal resolution multiplied by the aspect ratio.

The value of r_h does not depend on the dimensions of the scanning pattern but rather on the electrical performance of the television system in reproducing rapid changes of voltage whereby the reproducing scanning agent is changed in brilliance as it moves across each line. In terms of the maximum frequency f_{max} in the video range (see Sec. 16), the horizontal resolution is approximately

$$r_h = 84 f_{max} \quad \text{elements per picture height} \tag{5}$$

where f_{max} is expressed in megacycles. This expression assumes transmission at a rate of 30 frames per second and 525 lines. Horizontal resolution of 340 lines (f_{max} = 4.0 Mc) is attainable in properly operated equipment.

11. Resolution Ratio. The ratio of the horizontal resolution to the vertical resolution is the resolution ratio m:

$$m = \frac{r_h}{r_v} = \frac{84 f_{max}}{k n_a} \tag{6}$$

Unity resolution ratio (equal resolution in vertical and horizontal directions) is not essential for good reproduction; *i.e.*, the resolution in one direction may exceed that in the other without wasting the detail in the direction of higher resolution. In present practice the resolution ratio approaches 0.95, depending on the maximum frequency in the video range. For values of f_{max} = 4 Mc, n_a = 485 lines, and k = 0.75, the resolution ratio is 0.925.

FIG. 3. Relationship between horizontal resolution and maximum video frequency.

12. Total Number of Reproducible Picture Elements. A significant figure of merit of the television system is the total number, N, picture elements which may be accommodated in the picture area, *i.e.*, the product of the number of elements vertically r_v times the number horizontally $(w/h)r_h$:

$$N = \left(\frac{w}{h}\right) r_h r_v = \left(\frac{w}{h}\right) (84 f_{max})(k n_a) \tag{7}$$

$$= \left(\frac{w}{h}\right) m k^2 n_a^2$$

For values of $(w/h) = 4/3$, f_{max} = 4.0 Mc, n_a = 485 lines, and k = 0.75 (m = 0.925), the total number is N = 165,000 picture elements. Performance above 200,000 picture elements is exceptional in the present state of the art.

13. Viewing-distance Relationships. The desirable viewing distance of a television image depends on the resolution available. If we assume a visual acuity of 1 min of arc (typical of most normal eyes), two stationary dark picture elements separated by a bright element (Fig. 4) may be barely resolved by the eye at a distance d_c.

$$d_c = \frac{6{,}876 h}{k n_a} \tag{8}$$

and the corresponding ratio of critical viewing distance to picture height is

$$\frac{d_c}{h} = \frac{6{,}876}{k n_a} \tag{9}$$

For a vertical resolution $r_v = kn_a$ of 350 elements per picture height, the foregoing ratio is about 20 times. This is the maximum viewing distance (20 times the picture height), beyond which the eye is unable to resolve the detail actually present in a stationary image. In practice, since the picture elements are not sharply defined and since the act of following motion reduces visual acuity, full detail can rarely be resolved at distances greater than eight times the picture height.
FIG. 4. Critical viewing distance in terms of the dimensions of the scanning pattern.

The minimum viewing distance is determined by the tolerance of the viewer toward the structure of the picture, which becomes increasingly evident as the viewing distance is decreased. Viewing distances shorter than three times the picture height are seldom considered satisfactory. A ratio of 5:1 seems to be typical of viewer habits. Figure 5 shows Eq. (9) for various numbers of scanning lines.
FIG. 5. Viewing distance vs. number of scanning lines, in terms of picture height.

14. Frame-repetition Rate. The rate at which the frames are repeated (frame-repetition rate) depends (1) upon the duration of the persistence of vision of the eye and (2) upon the necessity of reproducing motion in the image in a smooth manner. In motion pictures the standard rate is 24 frames per second, with each frame projected twice, making 48 projection intervals per second. Similar values serve for television. However, since the power-supply frequency for most areas in this country is 60 cps, it is desirable to use a frame-repetition rate f which is a submultiple of the power frequency, *e.g.*, 30 per second (field repetition rate f' of 60 per second). The FCC standards for these items are

$$f = 30 \text{ frames per second} \qquad (10)^*$$

$$f' = 60 \text{ fields per second} \qquad (11)^*$$

15. Rate of Scanning Picture Elements. The maximum rate of scanning picture elements along each line equals the number of elements in the line divided by the time during which the line is scanned. These quantities in turn depend on the horizontal resolution (Sec. 10) and on the number of lines per frame (Sec. 5) and the rate of frame repetition (Sec. 14). The general expression for the maximum rate of scanning picture elements R is

$$R = \frac{w}{h} mfkn^2 \frac{(1 + b_h)}{(1 + b_v)} \quad \text{elements per second} \qquad (12)$$

where the quantities have been defined in the preceding sections. For aspect ratio $w/h = 4/3$, resolution ratio $m = 0.925$, frame-repetition rate $f = 30$ per second, utili-

zation ratio $k = 0.75$, number of lines per frame $n = 525$, horizontal retrace ratio $b_h = 0.20$, and vertical retrace ratio $b_v = 0.08$, the rate of scanning picture elements is approximately $R = 8{,}500{,}000$ elements per second, which is approximately the upper limit of performance of present-day equipment.

16. Maximum Frequency in Video Range. The maximum video frequency generated by the television camera is directly proportional to the rate at which the picture elements are scanned along each line. In deducing a relationship between the scanning rate R (Sec. 15) and the maximum video frequency (v.f.), it is customary to assume that the picture elements are arranged as alternate black and white squares along the scanning line. An ideal scanning agent, scanning such a line, will produce a square wave, as shown in Fig. 6. The upper portion of each square wave represents a black element, the lower portion an adjacent white element. Hence there are two elements per cycle of the wave. The fundamental frequency of the square wave is accordingly one-half as great as the rate of scanning picture elements. The maximum v.f. is then derived from Eq. (12), as

FIG. 6. Wave forms resulting from scanning a checkerboard image. The ideal square wave becomes a sine wave when only the fundamental frequency is transmitted.

$$f_{\max} = \frac{(w/h)mfkn^2}{2} \cdot \frac{(1 + b_h)}{(1 + b_v)} \tag{13}$$

For the conditions cited in Sec. 15, $f_{\max}$ is 4.25 Mc. Table 1 gives other typical values. It should be noted that this frequency is the fundamental of the square wave. The

Table 1. Maximum Video Frequencies for Different Scanning Patterns

No. of scanning lines, n	No. of frames per second, f	Max v.f. for equal vertical and horizontal resolution ($m = 1.00$), cps	Max v.f. for horizontal resolution = 0.9 × vertical resolution ($m = 0.9$), cps
20	16	3,360	3,020
60	16	30,200	27,250

525 (5 × 5 × 7 × 3)	30	4,350,000	3,920,000
1,029 (3 × 7 × 7 × 7)	30	16,650,000	14,800,000

NOTE: Calculation based on $w/h = 4/3$, $b_h = 0.143$, $b_v = 0.083$, $k = 0.75$.

reproducing equipment cannot reproduce a square wave of this frequency. Instead a sine-wave distribution of light is reproduced. This sine wave (Fig. 6) establishes the basic structure of the reproduced image.

17. Scanning Wave Forms. The deflecting forces necessary to produce the linear scanning motions shown in Fig. 2 are *saw-tooth waves*, as shown plotted against time

in Fig. 7. The forward motion in the horizontal direction is produced by a deflecting force linear with time, and the retrace motion by a force which need not be linear but which must have a rate of change high compared with that of the forward force. The ratio of the slopes is equal to the inverse of the horizontal retrace ratio b_h (Sec. 7). The same conditions apply to the deflecting force in the vertical direction, and the ratio of the retrace slope to the forward slope of this wave equals the inverse of the vertical retrace ratio, b_v.
FIG. 7. Saw-tooth waves of deflecting force used to produce the scanning pattern (525-line image).

The scanning wave forms have fundamental frequencies determined by the number of fields per second and by the number of lines per second. In the vertical direction the scanning force must repeat itself at the field repetition rate, $f' = 60$ cps. In the horizontal direction the deflecting force must repeat itself at the line-scanning frequency (525 lines per frame, 30 frames per second), which is the product

$$nf = 525 \times 30 = 15,750 \text{ cps}$$

These values of scanning frequency are the fundamentals of the saw-tooth wave. From 5 to 20 harmonics should be present if the wave form is to approximate the saw-tooth shape sufficiently accurately for scanning purposes. Figure 8 shows the degree of approximation for a saw-tooth wave having a retrace ratio of 0.15 when 5 and 15 harmonics are included. The fifteenth harmonic extends the range up to 900 cps for
FIG. 8. Ideal saw-tooth wave and approximations resulting from inclusion of 5 and 15 harmonics.

the vertical scanning system, and up to 250,000 cps for the horizontal scanning system. Practical scanning generators are discussed in Sec. 66.

VIDEO-SIGNAL WAVE FORM

18. Video Signal. The video signal (or "composite video signal") is the succession of electrical impulses transmitted through the television system to convey the information from the scanning agent in the camera to the scanning agent in the receiver. Three direct functions are carried out through the video signal: (1) the transmission of impulses corresponding to the brightnesses of the scanned picture elements, conveyed by the *camera signal;* (2) the blanking of the scanning agent at the receiver during the retrace motions, by the *blanking level* or *pedestal;* and (3) the synchronization of the scanning agents, by the *vertical* and *horizontal synchronization signals.* The first item of the video signal is generated in the camera, the second two in the *synchronization signal generator.* The three items are combined in the *video mixing amplifier.*

19. Envelope of the Modulated Picture-carrier Signal. When the video signal is imposed on a carrier wave, the envelope of the modulated carrier wave constitutes the video-signal wave form. Such a modulated picture carrier and the details of the envelope are shown in Fig. 9.

In the FCC standard video signal (Fig. 9) the carrier amplitude is divided by the black level (blanking level or pedestal) at 75 ± 2.5 per cent of the maximum amplitude. The amplitude region above the black level is called the *infrablack* region and is occupied by the synchronizing signals. Signal levels in this region do not produce light in the received image. The synchronizing signals (Fig. 12) are of two types: (1) horizontal signals for initiating the motion of the scanning agent along each horizontal line and (2) vertical signals for initiating the motion of the scanning agent vertically at the beginning of each field. The peak amplitude of the wave, the height of the synchronizing pulses, and the black-level amplitude are maintained constant throughout each broadcast at the values shown in Fig. 12.

20. Camera Signal. The portion of the carrier envelope extending below the black level is called the *camera signal.* The polarity of transmission in the FCC standard is negative; *i.e.*, an increase in the light on the camera plate results in a decrease in the carrier amplitude, as shown in Fig. 9. The maximum white level is 12.5 ± 2.5 per cent of the maximum carrier level. The black reference level is separated from the blanking level by the *setup* level, which is 75 ± 2.5 per cent of the video range from blanking level to reference white level. The setup level was established as an operating tolerance, the magnitude of which is a compromise between loss of picture-signal amplitude range and clipping of black signal peaks which exceed the blanking level. Intermediate gray tones exist between the reference maximum-white level and the reference maximum-black level. The various levels in the United States composite television signal, expressed as per cent modulation of the picture carrier, are shown in Fig. 9*a*.

A standard wave-form cathode-ray-tube monitor is used in the United States. It employs a scale using blanking level as the zero reference, reference white level as 100 per cent, and synchronizing peak level as about 40 per cent negative. The cover faces of the monitors are inscribed with this scale in conjunction with light horizontal reference lines. This scale is shown in Fig. 9*b*.

The carrier envelope corresponding to the FCC standard is shown in Fig. 9*c*.

The camera signal has two components (Fig. 10): an a-c component, which describes the variations in brightness from the average brightness; and the d-c component,
FIG. 9. (*a*) Standard carrier levels for U.S. composite television signals. (*b*) Calibration of cathode-ray-tube wave-form monitor. (*c*) Appearance of carrier envelope.

averaged over the frame-scanning interval ($\frac{1}{30}$ sec), which represents the average or background brightness of the picture. The a-c and d-c components must be capable of being varied independently of each other, so that the same detail may be presented either on a dark background or on a bright background. Variation of the d-c component also permits the screen brightness to be "faded in" or "faded out" at the will of the studio operator. In order that the d-c component be independent of the a-c component, regardless of the changes in wave form, it is necessary that the black level be constant in the carrier envelope, and furthermore that the black level be maintained constant at the control grid of the picture tube (see Sec. 60).
FIG. 10. A-c and d-c components of modulation envelope. Dashed line represents an increase in the background brightness without change in detail.
FIG. 11. Ideal phase and amplitude characteristics.

21. Frequency Range in the Video Signal. The maximum frequency in the video range (Sec. 16) results from scanning the finest detail in the image, *i.e.*, from the scanning of adjacent picture elements. The value of f_{max} [Eq. (13)] depends on the rate at which adjacent picture elements are scanned; values up to 4 or 5 Mc are commonly employed in present equipment.

The lowest frequency in the video range, f_{min}, depends on the rate at which the background brightness of the scene changes. Brightness changes which take longer than the duration of a single frame to complete themselves are usually introduced by changes in the d-c component of the signal. Changes that take less than the duration of a single frame are accommodated by video frequencies extending downward to 30 cps (corresponding to the frame-repetition rate of 30 per second). Consequently the significant frequency range in the video signal, based on the FCC standards, is from 30 cps to 4 Mc.

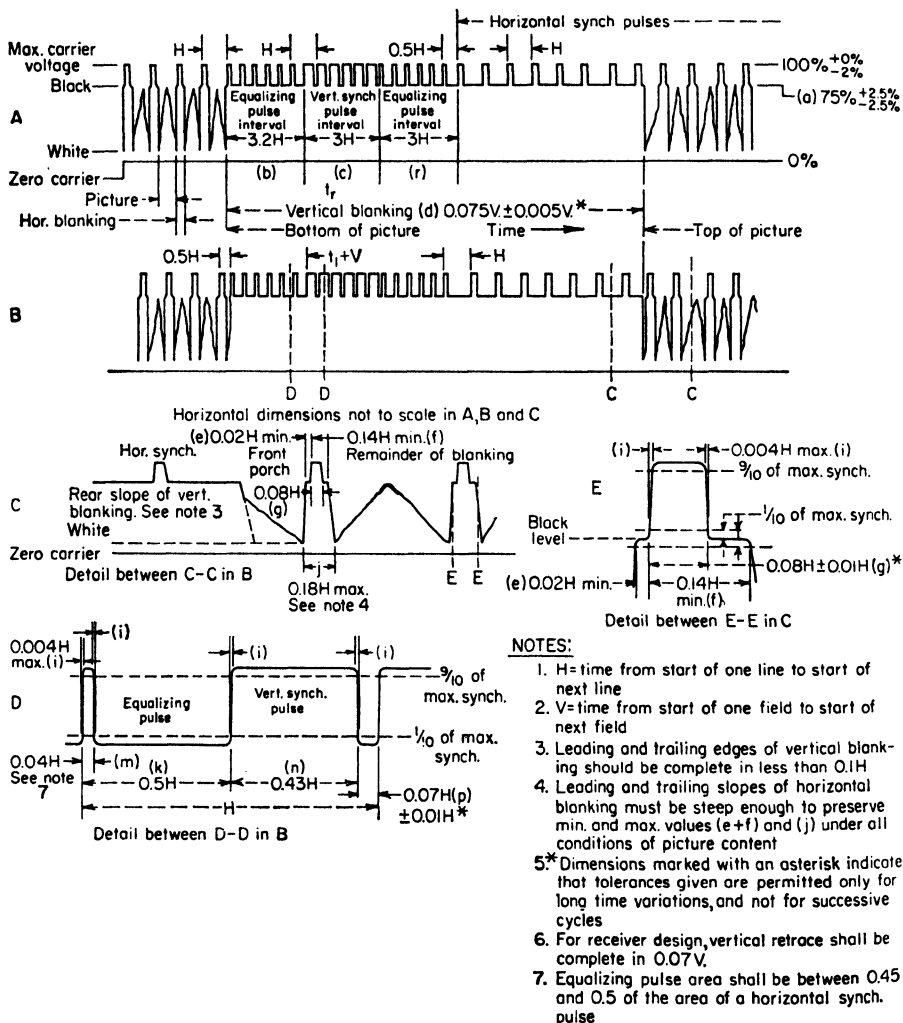
Degrees of picture detail intermediate between the whole frame area and the area of a single picture element are reproduced by frequencies intermediate between 30 cps and 4 Mc. Since such intermediate degrees of detail may be present in any scene, the video-signal transmission system must be equally responsive to all frequencies within these limits.


Fig. 12. Dimensions of the FCC standard video-signal wave form.

22. Requirements for Transmission of the Video Wave Form. Fourier analysis of wave forms reveals that any wave form encountered in practice is composed of a number of sine-wave components having specified relative amplitudes and specified relative phases. If the wave form is to be reproduced accurately, the transmission system must be capable of transmitting all such sine-wave components, throughout the v-f range, without altering the relative amplitudes and phases of the components. This

requirement is met if the amplitude-frequency response curve of the transmission system is a horizontal straight line over the v-f range, and if the phase-frequency curve of the transmission system is an oblique straight line passing through the zero-frequency point and extending over the v-f range. The ideal characteristics are shown in Fig. 11.

If the amplitude transmission characteristic is not ideal, the wave form is distorted symmetrically about a vertical axis. If the phase transmission characteristic is not

FIG. 13a. Synchronizing details of Gerber and U.S.S.R. systems. See Fig. 12 for notes.

ideal, the wave form is distorted asymmetrically about a vertical axis. Inadequate h-f response produces improper reproduction of steep vertical changes in the wave form. Inadequate l-f response produces improper reproduction of the flat top portions of the wave which extend over intervals comparable with the period of the low frequencies.

23. Dimensions of Synchronizing Pulses. The dimensions of the sync pulses in the FCC standard wave form are shown in Fig. 12. There are three distinct types of sync pulse. The *horizontal sync pulse* exists on the blanking pulse between the scanning of each line and occupies a duration of 8 per cent of the duration of the line-scanning interval. The *vertical sync pulse* exists on the blanking impulse between the scanning

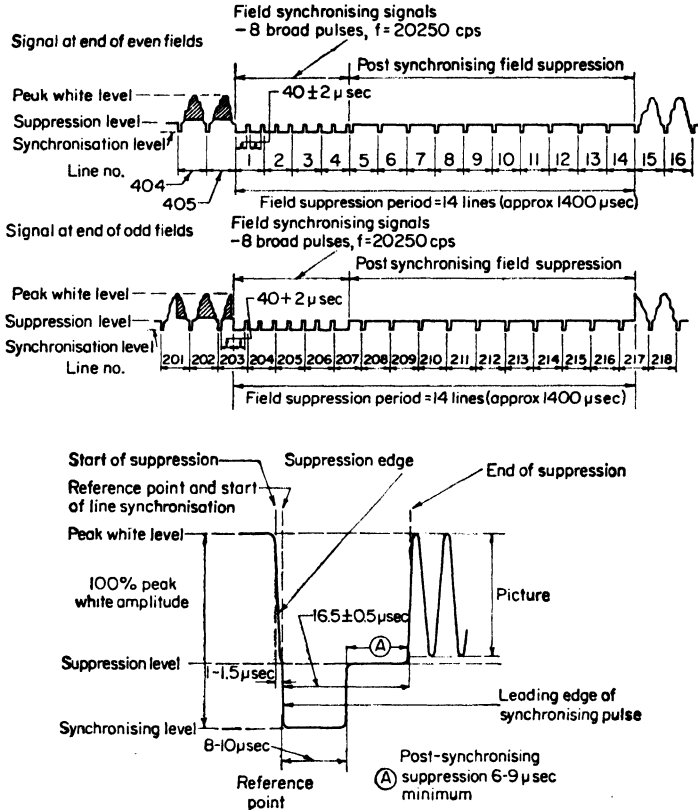
of successive fields and extends for three times the duration of the line-scanning interval. The *equalizing sync pulses* exist immediately before and after the vertical sync pulse in two groups of six pulses each. The frequency of the equalizing pulses is twice that of the horizontal sync pulses.


FIG. 13*b*. Synchronizing details of the British system. The hatched part of the signal shown can be occupied either by a suppression pulse up to two lines in length or by picture signal as shown. A small presynchronizing suppression pulse is shown at the opening of the frame suppression. This may be between 0 and 10 μsec in length. The signal is shown in its video form, but synchronizing level corresponds to 0 to 3 per cent. Suppression level 30 per cent ± 3 per cent, and peak white 100 per cent of carrier amplitude. Time of rise of synchronizing (10 per cent to 90 per cent), 0.25 μsec. Time of rise of suppression edge (10 per cent to 90 per cent) should not exceed 1 μsec. Minimum postsynchronizing suppression period 6 μsec. Field-suppression period 14 lines and variation must be such as not to cause visible jitter on picture. Field frequency is tied to frequency of power lines.

The horizontal scanning generators at transmitter and receiver are usually synchronized by the leading edge of the horizontal pulses. Since the synchronizing action must be precise, the leading edge must be sharp. The rise of this edge must complete itself in 0.4 per cent of the line-scanning interval.

The vertical scanning generators at transmitter and receiver are usually synchronized by the integrated effect of the equalizing and vertical sync pulses which are used to charge a capacitor. The leading edge of the capacitor charge curve (Fig. 45) acts as the synchronizing agent. This leading edge must have precisely the same shape for each vertical pulse. The equalizing pulses are inserted to ensure that this condition is met equally for fields ending on a half line and for fields ending on a whole line.

24. World Television Standards. There are eight recognized sets of television standards in use in the world. Some features are common to all but there are also many differences. In countries which use 50-cps electric power the field frequency is 50 and the frame frequency is 25. In other countries which use 60-cps power the field frequency is 60 and the frame frequency is 30. Television channel widths vary from 5 to 14 Mc. In Europe six different sets of standards are in use.

Table 2 shows important technical specifications of each set of standards and the countries in which they are used.

25. Composite Wave Forms of Other Television Systems. The composite wave forms and dimensions of systems in use which differ from those of the United States
FIG. 14. Channel arrangement for various systems.

system are shown in a series of figures. The Gerber and U.S.S.R. systems are illustrated in Fig. 13*a*. Figure 13*b*, *c*, and *d* shows, respectively, the British, French, and Belgian systems.

The following notes apply to Fig. 13.

1. H = time from start of one line to start of next line.
2. V = time from start of one field to start of next field.
3. Leading and trailing edges of vertical blanking should be complete in less than $0.1H$.
4. Leading and trailing slopes of horizontal blanking must be steep enough to preserve minimum and maximum values of $(x + y)$ and (i) under all conditions of picture content.
5. Dimensions marked with asterisk indicate tolerances and are for long-time variations and not for successive cycles.
6. Equalizing pulses shall be between 0.45 and 0.5 of the area of a horizontal sync pulse.

The manners in which the various systems differ in channel width and location of carriers are illustrated in Fig. 14.

26. Allocation of Television Channels. Frequency allocations for the radio services are the subject of international agreements. The bands assigned for television in the three regions of the world are shown in Table 3. The frequencies in

bands I, III, IV, and V assigned to the Western Hemisphere have been divided into 6-Mc channels in the United States and each channel is identified by a number, as shown in the table.

27. Standards Conversion. It is desirable to exchange programs among countries using different standards. System differences such as the line frequencies impose difficult problems. One difficulty arises when the camera-tube beam scans a different line structure, producing stroboscopic patterns, or line beating. Another difficulty arises when variations in field frequencies occur between the systems. Still another difficulty arises because the picture-tube display is an intensity-modulated light spot and not a continuous image. If the camera output were responsive to changes in total light flux of the picture tube, it would reflect changes in the picture-tube spot brightness and an unconverted component would be present in the output.

The most convenient method of conversion, and the one employed in Europe, is to use a picture-tube phosphor with sufficiently long persistence time, of the order of one field, to present to the camera a nearly continuous image. Zinc-beryllium silicate phosphor has been used with satisfactory results. The decay characteristic is such that the brightness field is reduced to 28 per cent of its original value during the interval of one field scan. This yields an improvement of 23 db over conventional picture-tube mixed sulfide phosphor in the ratio of converter signal to photosignal. Line beating is minimized by making the picture-tube spot size equal to the vertical distance between lines so that the line structure is rendered practically invisible. This could be accomplished by controlling the focusing circuits but it is more convenient to employ vertical spot wobble, which permits close control of the vertical spot coverage.

The signal to be converted is first applied to a stabilizing amplifier which (1) stabilizes black level and removes interfering signals such as hum, (2) makes available sync pulses at input signal rate for time-locking the display unit, and (3) applies high-frequency preemphasis to compensate for aperture losses in the picture tube. Flyback suppression is applied to permit the picture-display setup to be much beyond the area where flyback lines would normally be visible. An image-orthicon camera, employed for reading, is compensated for aperture losses prior to insertion of blanking.

Programs originated in Paris with the 819-line system were, in the past, converted to a 441-line system for domestic use. The 819-line picture is relayed by microwave radio to Cassel, France, where it is converted to the British 405-line system, following which the signal is again relayed by microwave radio to London for distribution over the British network.

Conversion by this method from the British 405-line picture to the French 819-line picture naturally will impose on the French system the limitations in picture detail of the British system, which inherently is of lower definition capabilities.[1]

GENERATION OF THE VIDEO-SIGNAL WAVE FORM

28. Video-signal Generator. This consists of three essential parts: (1) the camera and its auxiliaries, which generate the camera signal component, (2) the synchronizing signal generator, which times and shapes the vertical and horizontal synchronizing signals and the blanking signals, and (3) the control amplifier, which mixes the camera signals with the synchronizing signals and the blanking signals, forming the composite video signal.

29. Television Cameras. The television camera consists of a housing fitted with an adjustable lens which focuses the scene on the photosensitive plate of the camera tube enclosed within the housing. Also enclosed in the housing is a preamplifier which raises the level of the camera signal (usually to about 0.1 volt peak to peak) so that it can be transmitted over coaxial cable without interference. One or more scanning generators or scanning amplifiers may also be included in the camera housing. The camera is ordinarily mounted on a flexible standard so that it may be moved

[1] Martin, A. V. J., International TV Is Here, *Radio and Television News*, December, 1952. Lord, A. V., Standards Converter for International TV, *Electronics*, August, 1953.

readily, and a universal mounting is provided so that the camera may be directed at any angle. Some form of auxiliary monitor system is also provided to enable the operator to keep the image in focus.

At present there are three important types of electronic camera tubes in use in the United States: (1) the *iconoscope*, which is now used only for film projection, (2) the *image orthicon*, and (3) the *vidicon*. All these tubes make use of the storage principle in which the effect of the incident light is stored as charge across a capacitance element.

30. Iconoscope. A typical iconoscope is shown in Figs. 15 and 16 with its optical and electrical auxiliaries. The image is focused on the mosaic plate, which is a mica
FIG. 15. Optical arrangements used with the iconoscope camera tube.

sheet coated with several million globules of photosensitized silver, insulated from each other and from a metallic coating on the reverse side of the plate. The optical image releases electrons from the mosaic, thereby charging the plate positively with a charge distribution corresponding point for point with the distribution of light in the image. The insulation prevents redistribution of this charge and permits the charge image to increase in magnitude as the light continues to fall on the mosaic.

The mosaic is scanned by a beam of electrons generated in the electron gun in the side arm of the tube. The beam, impinging on the mosaic, releases secondary electrons. The number of secondary electrons released from a given point of the mosaic depends on the potential of that point, which in turn depends on the previous photoelectric emission from that point. Consequently, as the scanning agent passes over the mosaic, it generates a secondary emission current which corresponds to the successive values of brightness in the picture elements. The secondary emission is small for brightly illuminated portions of the mosaic; consequently the output current is "negative" with respect to the illumination responsible for it.
FIG. 16. Iconoscope electrical arrangements.

The secondary emission is collected by a collector anode and conducted through an external coupling resistor back to the metallic signal plate on the back of the mosaic support. The series circuit through which the electron current passes is accordingly composed of the ohmic resistance of the secondary emission path, the coupling resistance, and the capacitance between the signal plate and the group of globules under the scanning agent. No d.c. can flow through the capacitance; hence the output consists simply of the a-c component of the camera signal. The d-c component must be evaluated either by visual observation or by a phototube which integrates the light on the scene. A direct voltage derived from a manual control (or from the phototube in the second case) is inserted in series with the output of the iconoscope.

Since the mosaic is insulated, the current flowing toward or away from it must be zero, when averaged over any extended period of time. The average d-c value of the collected secondary emission must accordingly be replaced by electrons from the scanning beam.

Only a part of the secondary emission is collected from the mosaic. The remainder, falling back on the mosaic, sets up a distribution of charge which, when scanned, produces a spurious signal whose effect is to produce an unevenness in the background shading of the reproduced picture. This spurious signal ("dark-spot signal") must be compensated by a *shading-correction* signal generator (Sec. 38).

The color response of the typical iconoscope mosaic (when the mosaic has been silver sensitized) is very similar to that of the usual panchromatic negative-film emulsion used in motion pictures.

The sensitivity of modern iconoscopes under optimum conditions varies from about 1 mv per millilumen per sq cm illumination on the mosaic surface (low values of illumination) to about 0.25 mv (at higher illumination). The log-log curve between input illumination and output voltage of the typical iconoscope is characterized by an average slope (Sec. 71) of about 0.7. The output voltages may be increased by increasing the current used in the scanning beam, as well as by illuminating the interior of the tube envelope by a bias light.

31. Image Orthicon. The image-orthicon type of camera tube is almost universally used for live studio pickup and for televising outside events because of its great
Fig. 17. Image-orthicon construction.

sensitivity, excellent gray-scale reproduction, and over-all merit as a transducer. A diagram of it is shown in Fig. 17. The optical image is focused on the *photocathode*, just inside the glass envelope of the tube. This is a continuous surface of photosensitive material which emits electrons from its rear face in a distribution proportional to the lights and shadows of the image.

The photocathode is several hundred volts negative with respect to the *target electrode* (mosaic), which is located parallel to the photocathode and about 1½ in. distant. The electron image formed at the photocathode is accordingly drawn to the target. There the impinging electrons give rise to secondary emission, the secondaries being collected by a fine-mesh screen located adjacent to the surface of the target. The target thereby becomes charged with a distribution proportional to the brightnesses of the optical image, and the value of this charge is several times greater than the impinging electron image, by virtue of the electron multiplication which occurs in the act of secondary emission at the target surface.

The target is made of very thin glass having low resistivity. The lateral resistance is sufficient to preserve the charge configuration on the target for the duration of the frame interval. The target is scanned on its rear surface by a low-velocity beam of electrons in a manner identical to the scanning in the standard orthicon. Electrons are collected from the scanning beam by virtue of the positive-charge image on the reverse side of the target, and the variations thus imposed on the returning beam of scanning electrons constitute the video signal.

The electrons absorbed on the rear face of the target move through the target, by virtue of the low-resistance path offered by the glass. The charge image trapped on the forward face is thus neutralized and leaves the target prepared for the next scanning cycle.

The returning beam impinges on a target structure surrounding the electron gun, which leads to an electron multiplier. The amplified video current is collected at the output electrode of this structure and passed through the coupling resistor.

The image orthicon has a sensitivity several hundred times greater than that of the iconoscope, the limit of sensitivity being shot noise in the electron emission at the photocathode and at the target electrode. At threshold values of light, the image-orthicon exposure index exceeds manyfold that of the fastest photographic film; a recognizable image may be televised with it in the light of a match. The video signal is linearly related to the incident light up to a limiting value, at which a sharp saturation occurs. This permits the camera to be exposed to very widely varying levels of light without blocking or desensitizing the mosaic. The camera is very successfully used under marginal conditions of light like those encountered in televising outside events.

32. The Vidicon. The RCA vidicon is a small television-camera tube widely used for industrial puposes; for cameras for motion-picture film, transparencies, and
FIG. 18. General construction of the vidicon.

opaques; and in extremely small, compact, and portable cameras. Various models vary in size from 6¼ by 1.125 in. for 600-line-resolution high-quality film cameras to experimental models only about 3 by ½ in. having somewhat lower resolution. The construction of a vidicon tube is illustrated in Fig. 18. For film cameras the tube has a sensitivity permitting televising of motion-picture film with an average highlight illumination of 100 to 300 ft-candles on highlights on the face of the tube. For opaques and transparencies a constant illumination of 10 ft-candles on the face of the tube is adequate. The spectral response is similar to that of the human eye and the tube is excellent for use with film. Its small size and simplicity are added advantages in the design of film cameras and auxiliaries.

The tube (Fig. 19) has a transparent conducting film on the inner surface of the faceplate; a light-sensitive element consisting of a thin layer of photoconductive material deposited on the signal electrode; a fine-mesh screen (grid No. 4) located adjacent to the photoconductive layer; a focusing electrode (grid No. 3) connected to grid No. 4; and an electron gun for producing a beam of electrons.

Each element of the photoconductive layer is an insulator in the dark but becomes slightly conductive when it is illuminated and acts like a leaky capacitor having one plate at the fixed positive potential of the signal electrode and the other floating. When light from the scene being televised is picked up by an optical-lens system and focused on the photoconductive-layer surface next to the faceplate, each illuminated layer element conducts slightly depending on the amount of illumination on the element and thus causes the potential of its opposite surface (on the gun side) to rise

in less than the time of one frame toward that of the signal-electrode potential. Hence, there appears on the gun side of the entire layer surface a positive potential pattern, composed of the various element potentials, corresponding to the pattern of light from the scene imaged on the opposite surface of the layer.

The gun side of the photoconductive layer is scanned by a low-velocity electron beam produced by the electron gun. This gun contains a thermionic cathode, a control grid (grid No. 1), and an accelerating grid (grid No. 2). The beam is focused at the surface of the photoconductive layer by the combined action of the uniform magnetic field of an external coil or permanent magnet and the electrostatic field of grid No. 3. Grid No. 4 serves to provide a uniform decelerating field between itself and the photoconductive layer so that the electron beam will approach the layer in a direction perpendicular to it—a condition necessary for driving the surface to cathode potential. The beam electrons approach the layer at low velocity because of the low operating potential of the signal electrode.

When the gun side of the photoconductive layer with its positive-potential pattern is scanned by the electron beam, electrons are deposited from the beam in sufficient quantities until the surface potential is reduced to that of the cathode, and thereafter are turned back to form a return beam which is not utilized in this tube. Deposition of electrons on the scanned surface of any particular element of the layer causes a change in the difference of potential between the two surfaces of the element. When the two surfaces of the element, which in effect is a charged capacitor, are connected through the external signal-electrode circuit and the scanning beam, a capacitive current is produced and constitutes the video signal. The magnitude of the current is proportional to the surface potential of the element being scanned and to the rate of scan. The video-signal current is then used to develop a signal output voltage across a load resistor. The signal polarity is such that, for highlights in the film, transparency, or opaque, the grid of the first video-amplifier tube swings in a negative direction.

Alignment of the beam is accomplished by a transverse magnetic field produced by external coils located at the base end of the focusing coil.

Deflection of the beam is accomplished by transverse magnetic fields produced by external deflecting coils.

Figure 19 shows a photograph of the type of vidicon used for high-quality film cameras.

FIG. 19. Actual appearance of the vidicon.

33. Preamplifier. A typical preamplifier for use with an iconoscope is shown in Fig. 20. To preserve a high signal-to-noise ratio in the first stage, an effective value of about 300,000 ohms is used as the coupling resistance, with a shunt capacitance of about 8 $\mu\mu$f. The poor h-f response incident to this combination is compensated in the third stage, which employs a bifilar winding (L_2) to remove the effect of the impedance in the power supply. The second and fourth stages are conventional video-amplifier stages with flat response to 5 Mc. The output stage is a cathode-coupled stage having less than unity gain and presenting an output impedance which matches the characteristic impedance (65 ohms) of the coaxial cable. The camera signal is sent over this cable to the control amplifier for mixing with the synchronization impulses. The output of the shading-correction generator (Sec. 38) is inserted directly in series with the signal plate of the mosaic.

34. Synchronization Signal Generator. *Timing Unit.* The sync pulses (Fig. 12) must be properly timed and properly shaped. A typical timing unit is shown in Fig. 22. The unit produces two outputs at 60 and 15,750 cps (for the FCC standard

video signal). The 60-cps output is derived from the basic 15,750-cps oscillation by frequency multiplication and division; multiplication to 31,500 cps and division in four steps of 7 (to 4,500 cps), 5 (to 900 cps), 5 (to 180 cps), and 3 (to 60 cps). Frequency multiplication is carried out in a frequency-converter tube, the divisions occurring in multivibrators isolated by buffer stages.

FIG. 20. Circuit diagram of an iconoscope preamplifier.

FIG. 21. Low-noise cascode vidicon preamplifier having 8-Mc band width.

The locally generated 60-cps signal is then compared with the 60-cps voltage of the power system by feeding the two sources to a discriminator diode which develops a d-c voltage proportional to the amount and direction of the phase difference between the two sources. This d.c. is used in an a-f-c circuit to correct the frequency of the basic 15,750-cps oscillator from which the locally generated 60 cps is derived. In

FIG. 22. Typical synchronization-signal-generator timing unit for 525-line image.

this way the 15,750- and 60-cps outputs are maintained in synchronous relationship with each other and with the frequency of the power system.

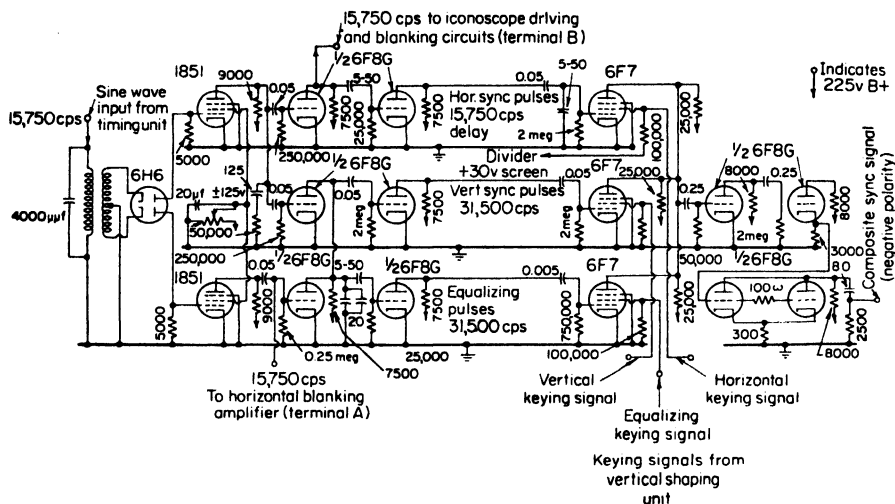
35. Synchronization Signal Generator. *Horizontal Shaping Unit.* Figure 23 shows one portion of the shaping unit of the sync signal generator, the horizontal shaping unit. This unit accepts the 15,750-cps output of the timing unit and produces from it the several wave forms required for the EIA standard signal (Fig. 12). The upper chain of tubes produces the horizontal sync pulses at 15,750 cps, the successive tubes being employed to obtain the required duration, shape, and steepness of front required for these pulses. The middle chain of tubes produces the serrated vertical sync pulses continuously at 31,500 cps. The bottom chain produces equalizing


FIG. 23. Typical horizontal shaping unit of a synchronization signal generator; 525-line image.

pulses at 31,500 cps. All three types of pulse are produced continuously in this portion of the generator. They are interspersed in the proper order (Fig. 12) by the action of keying signals in the 6F7 tubes at the right of each chain. The interspersed signal (composite sync signal) is then amplified by the stages at the extreme right and is applied to the control amplifier for mixing with the camera signal.

36. Synchronization Signal Generator. *Vertical Shaping Unit.* The vertical shaping unit (Fig. 24) has the function of producing so-called *keying signals* of 60 cps. These keying signals are applied to the screen grids of the keying tubes in the horizontal shaping unit. The action of the keying signals is to allow to pass, or to block, the sync signals passing through the keying tubes. Thus a negative keying signal is required to block the passage of the horizontal sync signals during the vertical blanking period (Fig. 12); a positive keying signal is required to allow the serrated vertical sync pulse to pass at the proper time during the field blanking interval; and a two-part positive keying signal is needed to allow the equalizing pulses to pass immediately before and after the vertical sync pulses. The shape of the keying signals and the synthesis of the composite sync signal are shown in Fig. 25. The vertical shaping unit accepts the 60-cps output of the timing unit and forms the required keying signals by several chains of shaping tubes which introduce the necessary wave shaping and delaying actions.

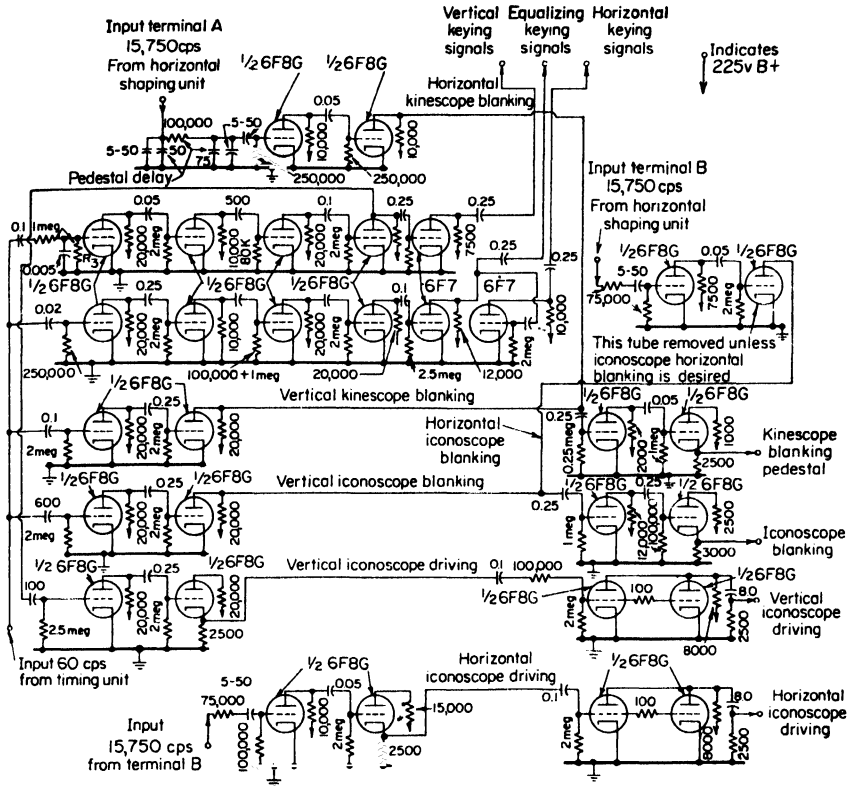
The vertical shaping unit also provides blanking signals which are applied to the control amplifier to introduce the black level during the retrace periods. Two sets


FIG. 24. Typical vertical shaping portion of synchronization signal generator for 525-line image.

of blanking signals are generated: one for the composite video signal and another, of somewhat shorter duration, for the control of the scanning beam in the camera tube. Each group of blanking signals consists of horizontal and vertical square waves recurring at 15,750 and 60 cps, respectively.

The camera-tube scanning generators are controlled by vertical and horizontal driving impulses, which are somewhat narrower and sharper than the corresponding sync pulses in the composite video signal. These driving pulses are formed from 15,750- and 60-cps signals derived from the horizontal and vertical shaping units, respectively.

FIG. 25. Function of the keying signals in interspersing the components of the composite synchronization signal.

37. Mixing Amplifier. The mixing amplifier (Fig. 26) has three input terminals which accept the camera signal from the camera preamplifier, the blanking signals, and the composite sync signals from the sync generator. The camera signal and blanking are first combined by means of two amplifier tubes feeding a common load resistor, across which the "semicomposite" signal appears. The d-c component of the video signal is controlled by varying the bias on the blanking-signal amplifier tube, thus controlling the amplitude relationship between the average of the camera-signal component and the blanking level.

The composite sync signal is similarly added to the camera and blanking components in two amplifier stages feeding a common load resistor, across which the composite video signal appears. Bias controls across these tubes control the relative amplitude

FIG. 26. Typical mixing video amplifier for combining camera signal, blanking signals, and composite sync signals.

of the camera and sync signal amplitudes, thus allowing the establishment of the 75–25 per cent relationship demanded by the standard signal.

38. Shading-correction Generator. The shading-correction generator is a device for producing wave shapes of saw-tooth, sine, and parabolic shape at vertical scanning and horizontal scanning rates (60 and 15,750 cps, respectively) in synchronism with the scanning motion. These wave shapes, controlled as to amplitude, phase, and polarity, are introduced in the preamplifier (Fig. 20) to compensate the spurious shading signal generated in the iconoscope. A form of shading-correction generator is shown in Fig. 27. The horizontal saw-tooth generator used to deflect the beam in the iconoscope tube is used directly to produce saw tooths of controlled amplitude and polarity, as well as 15,750- and 31,500-cps sine waves of controllable amplitude, phase, and polarity. Similarly the output of the vertical saw-tooth generators is used to produce similar signals. Reversal of polarity is provided by an amplifier stage. The switches control the polarity, resistors R_1, R_3, R_5, R_6, R_8, and R_{10} control amplitude, and resistors R_2, R_4, R_7, and R_9 control the phase. Methods of producing saw-tooth waves of controllable phase are also available, using "clipped-off" portions of the basic saw-tooth waves. The shading-correction-generator controls are manipulated man-

FIG. 27. Typical shading-correction signal generator.

ually to correct for the observed defects of shading in the image as viewed on the monitor picture tube.

VIDEO AMPLIFICATION

39. Requirements for Video Amplification. The system must transmit all sine-wave components within the video range, *e.g.*, 30 cps to 4 Mc, without amplitude discrimination and without phase discrimination. The gain G of a pentode amplifier stage (plate resistance large compared with the load resistance) is

$$G = g_m Z_0 \tag{14}$$

where g_m is the grid-plate transconductance of the tube, and Z_0 is the output impedance of the coupling connection between the stage and the following transducer. Over

the video range g_m is independent of frequency; hence the amplitude and phase responses of the amplifier are determined solely by Z_0.

In video amplifiers, Z_0 consists of R, L, and C components so proportioned as to display a constant magnitude of impedance and a phase angle proportional to frequency over the video range. The lower frequency limit over which these conditions may be met is determined by the series impedance of the coupling capacitor, whereas the h-f limit is determined by the shunt impedance of the capacitance existing in shunt across the coupling connection. The gain within these limits depends on g_m and on the value of the load resistor, since this is the principal component of Z_0 within the video range.

40. H-f Compensation. To minimize the effect of the shunt capacitance, it is usual in video amplifiers to insert a small inductance either in series with the load resistor (shunt peaking), in series with the coupling connection (series peaking), or a combination of the two (shunt-series peaking). The inductance is used to form a resonant circuit with the shunt capacitance at a frequency above the upper limit of the required v-f range, and the rising resonance characteristic is used to counteract the falling off of the Z_0 value at the upper frequency limit. The load resistor must similarly be chosen in terms of the total shunt capacitance, so that the gain in the mid-frequency range (where reactive effects are not prominent) will be the same as at the upper limit (where reactive effects are predominant).

In all cases of h-f compensation the basic factor is the total shunt capacitance C_t associated with the coupling connection

$$C_t = C_{gk} + C_{pk} + C_{gp}(G + 1) + C_{\text{stray}} \tag{15}$$

where C_{pk} = output tube capacitance
C_{gk} = input capacitance of following tube
C_{gp} = grid-plate capacitance of following tube
G = stage gain of following stage
C_{stray} = total shunt capacitance due to wiring, tube sockets, terminals, etc.

In pentode amplifiers, C_{gp} may ordinarily be neglected.

41. Shunt-peaking Compensation. The most widely used h-f compensation scheme (Fig. 28) is known as *shunt peaking*, because the resonating (peaking) inductance L_0 is in shunt across the shunt capacitance C_t. The design values of L_0 and R_0 (the load resistor) are based on the shunt capacitance C_t, on the maximum required frequency in the video range $f_{\max}$, and on two design constants k_L and k_R which relate the impedance of L_0 and R_0, respectively, to the impedance of C_t at the maximum frequency $f_{\max}$.
Fig. 28. H-f compensation by the shunt-peaking method, with equivalent circuits for high and low frequencies.

$$k_R = \frac{R_0}{1/(2\pi f_{\max} C_t)} \tag{16}$$

$$k_L = \frac{2\pi f_{\max} L_0}{1/(2\pi f_{\max} C_t)} \tag{17}$$

The values of k_R range from 0.8 to 1.0; most designs are based on $k_R = 1$; *i.e.*, the load resistance is made equal to the impedance of C_t at the maximum v.f. The values of k_L range from 0.3 to 0.7, but most designs are based on $k_L = 0.5$; *i.e.*, impedance of the inductance L_0 is made one-half as great as the impedance of C_t at $f_{\max}$. This is equivalent to making the resonant frequency between L_0 and C_t equal to 1.41 times $f_{\max}$.

On the assumption that $k_R = 1.0$, the gain at frequency f of the shunt-compensated video amplifier is

$$G = \frac{g_m R_0\{1 - j[k_L^2(f/f_{\max})^3 + (1 - k_L)(f/f_{\max})]\}}{(f/f_{\max})^2 + [k_L(f/f_{\max})^2 - 1]^2} \tag{18}$$
Fig. 29. Gain of a shunt-compensated video amplifier.

The absolute magnitude of this equation is plotted in Fig. 29, and its phase angle in Fig. 30, for several values of k_L.

Simplified design equations for shunt peaking ($k_R = 1$ and $k_L = 0.5$) are:

$$R_0 = \frac{1}{2\pi f_{max} C_t} \tag{19}$$

$$L_0 = 0.5 C_t R_0^2 \tag{20}$$

Typical values of R_0 are 2,000 to 4,000 ohms and of L_0 are 50 to 100 μh.

42. Series-peaking Compensation. The compensation in Fig. 31 has an advantage over the shunt-peaking system in that the inductance L_c isolates the effects of the output and input capacitances C_0 and C_i, whereas in the shunt-peaking systems, C_0 and C_i are directly additive. Since C_0 is less than C_t, for a given h-f limit R_0 may be made correspondingly larger; hence the gain of the stage is increased. On the assumption that $C_i/C_0 = 2$ (usually assumed condition), the design equations for R_0 and L_c are as follows:

Fig. 30. Phase angle introduced by a shunt-compensated video amplifier.

$$R_0 = \frac{1.5}{2\pi f_{max}(C_0 + C_i)} \tag{21}$$

$$L_c = 0.67 C_t R_0^2 \tag{22}$$

With these values the gain is uniform up to f_{max}, and its value is 50 per cent greater than the gain of the shunt-compensated stage with the same values of C_0, C_i, and C_t, provided $C_i/C_0 = 2$.

Fig. 31. Series-peaking system of h-f compensation.

43. Shunt-series-peaking Compensation. The combination of shunt and series peaking (shown in Fig. 32) allows still higher gain by combining the virtues of both connections. Assuming $C_i/C_0 = 2$, the design equations are:
FIG. 32. Combined shunt- and series-peaking systems.

$$R_0 = \frac{1.8}{2\pi f_{\max} C_t} \quad (23)$$

$$L_0 = 0.12 C_t R_0^2 \quad (24)$$

$$L_c = 0.52 C_t R_0^2 \quad (25)$$

The stage displays up to $f_{\max}$ uniform gain, which is 80 per cent greater than that of the simple shunt-peaking stage. The relative merits and design factors of the three methods of h-f compensation are shown in Table 4.

Table 4. High-frequency Compensation Systems

Type	R_0	L_0	L_c	Relative gain at $f_{\max}$	Variation in time delay, sec up to $f_{\max}$ cps
Uncompensated	$1/(2\pi f_{\max} C_t)$	....	....	0.707	$0.035/f_{\max}$
Shunt	$1/(2\pi f_{\max} C_t)$	$0.5 C_t R_0^2$	....	1.0	$0.023/f_{\max}$
Series ($C_i/C_0 = 2$)	$1.5/(2\pi f_{\max} C_t)$	....	$0.67 C_t R_0^2$	1.5	$0.0113/f_{\max}$
Shunt-series ($C_i/C_0 = 2$)	$1.8/(2\pi f_{\max} C_t)$	$0.12 C_t R_0^2$	$0.52 C_t R_0^2$	1.8	$0.015/f_{\max}$

44. L-f Compensation. The amplitude response of conventional RC-coupled amplifier stages at low frequencies is usually satisfactory, but the phase response at low frequencies is troublesome.

The phase angle introduced by C_c and R_g (Fig. 33) is sufficient to prevent proper reproduction of square waves of 30 or 60 cps fundamental frequency, unless very large values of C_c and R_g are employed. Large values of C_c introduce shunt capacitance to ground, and large values of R_g introduce grid-current difficulties. Large values of C_cR_g may induce relaxation oscillations. Accordingly it is usual to compensate the effect of the time constant C_cR_g by the introduction of a filter R_FC_F shown in Fig. 33.
FIG. 33. RC l-f compensation.

$$\frac{C_F R_0 R_F}{R_0 + R_F} = C_c R_g \quad (26)$$

When this condition is met, the gain at low frequencies is

$$G = \frac{(f/f_F) g_m R_0}{f/f_F - j} \quad (27)$$

where G = gain at frequency f
$f_F = 1/(2\pi C_F R_F)$
$j = \sqrt{-1}$

The amplitude and phase of Eq. (27) are shown in Figs. 34 and 35. Values of R_FC_F from 0.15 to 0.5 should be used to keep the point of zero-phase shift below 30 cps, as indicated in Fig. 35.

45. Cathode-coupled Stage. For many purposes a video-amplifier stage displaying low output impedance is necessary (to match the impedance of coaxial cables and to permit the stage to feed many high-impedance sources at once). The cathode-coupled stage (Fig. 36) is commonly used for this purpose. The gain of this stage is less than unity, and its output impedance can be designed readily for values as low as 50 ohms. The amplifier, being degenerative, has lower values of input capacitance, is freer from
FIG. 34. Amplitude response of l-f compensation system.
FIG. 35. Phase response of l-f compensation system.

amplitude distortion, and is less affected by changes in supply voltages than is the conventional amplifier stage.

The gain of the cathode-coupled stage is

$$G = \frac{\mu R_k}{r_p + R_k(\mu + 1)} \tag{28}$$

where μ = amplification factor of tube
r_p = its internal plate resistance
R_k = value of cathode resistor

The effective output impedance Z_0 is

$$Z_0 = \frac{R_k r_p/(\mu + 1)}{R_k + r_p/(\mu + 1)} \tag{29}$$
FIG. 36. Fundamental cathode-coupled stage.

An important practical advantage of the cathode-coupled stage is that it may be coupled to the following transducer without the intervention of a coupling capacitor, so that the d-c as well as a-c components of the video signal are transmitted. No pains need be taken to preserve the h-f response, since the low value of impedance makes the shunting effect of the output capacitance negligibly small.

46. Transient Response of Video Amplifiers. The response of a video amplifier to the Heaviside unit pulse of voltage is a general criterion of video-amplifier response.

The response to a single unit pulse is difficult to measure experimentally, but a square wave may be used as the exciting voltage, provided that the period of the wave is long compared with the duration of the transient response. Responses calculated on this assumption are shown in Fig. 37 for a single stage and for several multistage amplifiers. Simple shunt peaking is assumed, for various values of the

parameter $K = RC\sqrt{LC}$, *i.e.*, the ratio of the load resistor R_0 to the impedance of the shunt capacitance C_t at the frequency at which L_0 and C_t are resonant. The case for $K = 1.41$ is equivalent to the cases of $k_R = 1$ and $k_L = 0.5$ (Sec. 41).

47. Noise Limitations to Video Amplification. One of the principal limitations to proper video amplification is inadequate signal/noise ratio. The two sources of cir-

cuit noise, thermal agitation and shot effect, are evaluated in Figs. 38 and 39 for a transmission system responsive to the video range. Values of 50 to 100 μv are common. For a signal/noise ratio of 10:1, commonly assumed as the minimum acceptable for entertainment purposes, the desired signal must accordingly have an rms amplitude of from 0.5 to 1.0 mv.
